Conclusions: These findings show how the rhythmic structure of social communication impacts looking behavior in TD children, increasing TD children's looking to the eyes, time-locked with their communicative partner. When that rhythmic structure was disrupted, however, TD toddlers were less able to synchronize their looking to the eyes during important moments of social-communicative signaling. For children with ASD, the implication of these results is that children who struggle to perceive the rhythmic structure of social communication may consequently miss important social signals. Results for toddlers with ASD (data collection ongoing) will be discussed.

226 **169.226** Social Visual Preferences in Children with ASD: Preliminary Results from a Novel Dynamic Eye Tracking Task

M. C. Aubertine[1], *B. Li*[2], *M. Kim*[3], *E. Barney*[4], *Y. A. Ahn*[5], *J. C. Snider*[3], *A. Atyabi*[6], *T. Falck-Ytter*[7], *P. Nyström*[8] *and F. Shic*[4], *(1)Seattle Children's Hospital and Research Institute, Seattle, WA, (2)Computer Science and Engineering, University of Washington, Seattle, WA, (3)Seattle Children's Research Institute, Seattle, WA, (4)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (5)University of Miami, Miami, FL, (6)Seattle Children's Research institute University of Washington, Seattle, WA, (7)Karolinska Institutet & Uppsala University, Uppsala, Sweden, (8)Uppsala University, Uppsala, Sweden*

Background: Several eye-tracking studies have used social-nonsocial visual preference paradigms, i.e. side-by-side presentations of a social target versus a non-social distractor, to highlight atypical biases towards social information in individuals with autism spectrum disorder (ASD) (Pierce et al., 2011, 2015; Klin et al., 2009; Shaffer et al., 2017). In an ongoing study, we explore a modification of traditional social visual preference paradigms that incorporates uniform movement of targets and distractors, with the ultimate goal of increasing visual engagement to preference paradigms by participants while providing additional information for facilitating derivation of key eye tracking outcome measures.

Objectives:

- To examine the potential and limitations of a dynamic eye tracking social preference task in studying between-group differences in children with ASD and typically developing (TD) children.
- To examine relationships between social preferences in our task and clinically-relevant phenotypic variables in children with ASD.

Methods:

Twenty-nine children (N = 14 ASD, N = 15 TD) between the ages of 2 to 12 years watched three, 20 second trials. In each trial, two smaller videos were displayed: a social target video of a woman singing a song (Trials 1 and 3) or smiling (Trial 2), contrasted with distractor video of a nonsocial, dynamically evolving fractal. These videos began in the middle of the screen and moved horizontally in opposite directions, reversing towards the edge of the screen, and crossing over each other twice per trial. Videos were shown in the same order for every participant. Eye tracking was performed using an SR EyeLink 1000 Plus eye tracker.

Results:

An independent samples t-test showed that, across trials, the percentage of time TD children looked at the social stimuli (SocialLooking%) was greater than children with ASD (p =.042). However, when trials were examined individually, ASD and TD only significantly differed in Trial 1 (p = .046), not in Trials 2 and 3 (p = .082, 0.158). We subsequently performed a time course analysis, dividing comparable Trials 1 & 3 into four, equal time periods. A repeated measures ANOVA revealed TD children showed higher %SocialLooking only during time period one (p = .017). Phenotypically, relationships between ADOS and SocialLooking% in Trial 1 approached significance (r= -.480, p = .09). Age was negatively correlated with SocialLooking% in Trial 1 (r = .387, p = 0.035) and Trial 3 (p < .001).

Conclusions:

As predicted, children with ASD looked at the social stimuli less than TD children. Further exploration indicated these differences only occurred in the first portion of the first trial. It may be that TD and ASD differ only in initial, spontaneous preference for social stimuli, after which point familiarity effects wash away group differences. Results between social looking and autism symptoms are promising, but the current study may yet be underpowered to robustly detect these relationships. Relationship of age to social looking warrants caution, signalling the need to carefully consider developmental norms in this and potentially other preferential looking paradigms.

227 **169.227** Specificity of Social Visual Engagement Patterns in Toddlers with Autism Spectrum Disorder and Williams Syndrome

J. A. Olmstead[1,2,3], *A. L. Ford*[2,3,4], *W. Jones*[1], *A. Klin*[1], *M. D. Lense*[5], *S. Shultz*[1] *and S. K. Markert*[6], *(1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Department of Pediatrics, Emory University School of Medicine, Atlanta, GA, (3)Children's Healthcare of Atlanta, Atlanta, GA, (4)Marcus Autism Center, Atlanta, GA, (5)Vanderbilt University Medical Center, Nashville, TN, (6)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta & Emory School of Medicine, Atlanta, GA*

Background: The social phenotypes of Autism Spectrum Disorder (ASD) and Williams Syndrome (WS) are often contrasted with one another (Bellugi, 2001): in general, individuals with ASD are characterized as possessing reduced social interest, whereas those with WS are characterized as atypically prosocial and initiating. The present study seeks to investigate patterns of social visual engagement in groups of toddlers with ASD or WS. By gathering information about where a young child looks, we also gather information about his or her cumulative social experience and interests. Contrasting groups of young children with ASD and WS—both affected by social disability, but in seemingly opposite ways—allows unique insight into distinct, possibly disorder-specific avenues of early social development. Thus, by quantifying patterns of social visual engagement, we can further broaden our understanding of the specificity of early social disability in individuals with ASD.
Objectives: To quantify profiles of social visual engagement in toddlers with distinct diagnoses (ASD, WS, or non-ASD developmental delays (DD)) relative to a comparison sample of typically developing (TD) toddlers.

Methods: Twenty-four-month-old children were eye-tracked while viewing video scenes of naturalistic caregiver interactions. Diagnoses were made by experienced clinicians blind to experimental eye-tracking data, with genetic testing to confirm the WS deletion. All participant groups were matched on chronological age. Percentage of fixation time to 4 regions of interest (eyes, mouth, body, and object) were calculated for each participant. Fixation patterns were compared between groups using two-tailed independent samples t-tests.

Results: Toddlers with WS fixated significantly more on eyes compared to the ASD, DD, and TD groups (all p's < 0.01, **Figure 1a**). By contrast, toddlers with ASD exhibited a trend toward less time spent looking at eyes compared to all other toddler groups (p=0.094, **Figure 1a**). Toddlers with WS also fixated significantly less on the mouth region relative to all other groups (all p's < 0.01, **Figure 1b**). Toddlers with ASD showed a trend towards increased fixation on the body region relative to TD toddlers (p=0.057, **Figure 1c**). Finally, both ASD and WS groups spent more time looking at objects relative to TD toddlers (both p's < 0.05, **Figure 1d**).

Conclusions: Data from ASD and WS toddlers reveal marked and group-specific deviations from the fixation patterns observed in typical development. Toddlers with WS display a striking preference for looking at the eyes of others, whereas toddlers with ASD trend towards less eye-looking. In short, although toddlers with ASD share aspects of social and intellectual disability with WS and DD cohorts, respectively (see clinical characterization scores in Table 1), our results reveal the *specificity* of reduced eye-looking to the social phenotype of ASD, as well as aspects of atypical social visual engagement—such as increased attention to objects—that may be *common* to developmental delays characterized by social disability. These results highlight distinct mechanisms by which developmental outcomes precipitate in ASD and may ultimately point toward different paradigms of treatment for young children with Autism Spectrum Disorder.

228 **169.228** Temperamental Differences between Autistic and Typical Children : A Meta-Analysis

E. L. Bussières[1]*, J. P. Lemelin*[2] *and M. Couture*[3]*, (1)Psychology, Université du Quebec à Trois-Rivières, Trois-Rivières, QC, Canada, (2)Psychoeducation, Université de Sherbrooke, Sherbrooke, QC, Canada, (3)Rehabilitation, Universite de Sherbrooke, Sherbrooke, QC, Canada*

Background:
Although autism is no longer considered a rare condition, challenges remain in the diagnosis process due to an important clinical heterogeneity in the phenotype. Some authors have suggested that temperament may be a useful construct for understanding early developmental differences in infants at risk for ASD.

Objectives: The present meta-analysis aimed to determine if ASD children differed from normative children on three temperamental factors (Negative Affectivity, Surgency and Effortful Control).

Methods:

A comprehensive literature search was conducted to identify published articles and unpublished dissertations using six electronic databases: ProQuest, Google Scholar, Medline, PsycInfo, Cinhal, Embase, using the following keywords : autis* OR ASD OR “autism spectrum disorder” OR Asperger OR TED OR PDD AND temperament*. Literature search covered a period of time from January 1st, 1970 to July1st, 2017. To be selected for this meta-analysis, a study had to (a) include a sample of autistic children aged between 2 and 16 years old, which was compared to a normative group ; (b) assess child temperament with validated temperament questionnaires. Studies also had to meet minimal criteria regarding participant ascertainment, such as having a confirmed diagnosis of autism spectrum disorder derived from a standard method (e.g. ADOS) or by a mental health professional. Studies including high-risk siblings (not diagnosed with ASD) were not retained, in order to limit potential bias and heterogeneity among studies. Analyses were performed using the Comprehensive Meta-analysis software 2.0 (Borenstein, Hedges, Higgins, & Rothstein, 2005). Based on Borenstein and colleagues (2009) recommendation, when original studies compare two groups and differences between their means are available, we used Cohen’s d to transform and combine every available statistics.

Results: Twenty-one studies were included in this meta-analysis. Results showed that autistic children and normative children differed significantly on the Negative Affectivity (d= -.36; k=19; 95%CI: -.57 to -.15; Q= 127.14; p < .001) and the Effortful Control factors (d= -.65; k=20; 95%CI: -.93 -.36; Q= 244.74; p < .001). No differences emerged for the Surgency factor (d = -.24; k=20; 95%CI: -.54 to .54; Q= 246.53; p < .001). Further analyses showed that these associations are moderated by age, country and publication year.

Conclusions:

This meta-analysis confirms that autistic children show both higher levels of Negative Affectivity (greater temperamental reactivity) and lower levels of Effortful Control (less capacities to regulate this reactivity), in comparison to normative children. Temperament could thus be an important variable to consider and document to help identify children who are at a higher risk of having ASD.

229 **169.229** The Adaptive Value of Attending to Social Stimuli Differs for Toddlers with Autism Spectrum Disorder and Williams Syndrome

S. K. Markert[1]*, J. A. Olmstead*[2]*, A. L. Ford*[3]*, A. Klin*[2]*, C. Klaiman*[2]*, M. D. Lense*[4]*, W. Jones*[2] *and S. Shultz*[2]*, (1)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta & Emory School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Marcus Autism Center, Atlanta, GA, (4)Vanderbilt University Medical Center, Nashville, TN*

Background: Throughout the first years of life, infants filter environmental information by attending to what they find most important, creating a unique subjective experience that shapes their developing cognition. Both children with Autism Spectrum Disorder (ASD) and William’s Syndrome

(WS) exhibit intellectual, linguistic, and social disability, but with distinct phenotypic profiles emerging by the second year of life. Children with ASD exhibit reduced interest in the social world, manifested in both impaired social interaction and communication, as well as atypical patterns of visual attention to social stimuli. Contrariwise, children with WS appear to demonstrate a heightened interest in the social world, manifested in hyper-sociability, visual attentional preference to faces and eyes, and although delayed, linguistic aptitude to communicate with others. By identifying disorder-specific patterns of social visual engagement (i.e., the ways in which children actively seek information in the world and then use or fail to use that information as a route to social adaptation), this study aims to gain insight into the distinct developmental processes underlying each of these neurodevelopmental disorders.

Objectives: To investigate: (1) clinical profiles and patterns of visual fixation to social stimuli in children with ASD, WS, and control groups and (2) whether and to what extent fixation patterns are related to communicative competence.

Methods: Eye-tracking data were collected while 63 toddlers (20 ASD, 11 WS, 12 DD and 20 TD; refer to Table 1 for group characterization details) watched video scenes of an actress caregiver engaging in child-directed communication. Visual fixation was quantified as the percentage of time spent looking at 4 regions of interest (eyes, mouth, body, object). Between-group comparisons of assessment scores on the Autism Diagnostic Observation Schedule (ADOS) and the Mullen Scales of Early Learning were made, and within-group analyses tested for correlations between assessment scores and percentage of fixation time to each region of interest.

Results: Clinical profiles of toddler groups are presented in Table 1. For children with WS, percent fixation on the mouth was positively correlated with expressive ($p = .003$) and receptive ($p = .04$) language scores (Figure 1). The same significant positive correlations were found for both DD and TD control groups (all p's < .05). By contrast, mouth-looking was *not* correlated with either expressive or receptive language for children with ASD (all p's > 0.2).

Conclusions: This research reveals a disorder-specific developmental process that may contribute to the social and cognitive phenotype of ASD. Visual engagement with the mouths of others is positively associated with language competence for WS, DD, and TD groups alike. However, this type of visual engagement does not share the same adaptive value for children with ASD, who show no association between mouth-looking and language scores. This suggests that toddlers with ASD may seek and attend to the mouths of others for very different reasons than do TD, DD, and WS children. These very different goals likely yield different learning experiences and expertise that may contribute to the unique presentations of both neurodevelopmental disorders, and ASD in particular.

230 **169.230** The Effect of Exposure on Attitudes Towards Bullying and Autism in Schools

A. Cook[1]*, J. Ogden*[1]*, N. Winstone*[2] *and I. Dale*[3]*, (1)Psychology, University of Surrey, Guildford, United Kingdom, (2)Higher Education, University of Surrey, Guildford, United Kingdom, (3)The National Autistic Society, Sheffield, United Kingdom*

Background: Children with special educational needs are significantly more likely to be the victims of bullying. Many of the characteristics considered to be the prime causative factors of bullying are often typical of children with autism, for example, communication difficulties, inappropriate social behaviour, low social status and reduced social competence. 40% of children with autism are bullied at school (DfE, 2014) and 70% of children with autism are educated in mainstream schools. Little research, however, explores the impact of inclusion on the attitudes of young people *without* special educational needs towards their peers with autism in mainstream schools. School climate can influence the extent to which peers hold inclusive or exclusive peer-group norms and these in turn can influence reactions to bullying, moderate emotions and predict intended behaviours.

Objectives: This study aimed to explore whether there are differences in attitudes towards the bullying of different targets (autistic and neuro-typical) and different violations (verbal bullying and social exclusion) in contrasting school settings: high explicit exposure to autism (schools with centres for autism) and low explicit exposure to autism (no centre). It also aimed to explore cognitive attitudes towards people with autism according to school setting and level of personal exposure to people with autism.

Methods: Survey data were collected at the beginning and end of the school year from 775 children (384 male), aged 11-12, from six mainstream schools: three with high explicit exposure and three with low explicit exposure to autism. Participants read vignettes depicting bullying scenarios then completed measures of their judgements, emotions and intended behaviours in relation to the vignette and also their cognitive attitudes towards people with autism.

Results: Analysis indicated no significant differences by school (explicit) exposure, but did reveal a significant increase in prosocial attitudes towards people with autism with increased personal exposure.

Conclusions: The research question asked whether a particular model of inclusion can influence the attitudes of neuro-typical children towards their peers with autism. Studies of group identity have shown that exclusive peer in-group norms lead to an increased likelihood that children will engage in bullying towards out-group children whereas an inclusive normative climate can reduce intergroup bias. While this study found no difference in attitudes by school type, this particular model of inclusion was only recently established, and would benefit from a longitudinal research design to explore whether an inclusive normative climate can be developed to stimulate increases in prosocial attitudes over time. The difference in attitudes by personal exposure also highlights the importance of positive contact at a personal level, and has implications for future school interventions embracing the contact hypothesis to instil greater understanding and acceptance, and potentially make an impact on the lives of young people with autism.

231 **169.231** Theory of Mind and Intelligence: The Importance of Visual Stimulus in Autism.

D. Girard[1] *and* ***I. Garcia-Molina***[2]*, (1)Psychology, University of Quebec in Montreal, Montréal, QC, Canada, (2)Psychology, Universitat Jaume I., Castellón, Spain*

Background: Theory of mind (ToM) is the ability to attribute mental states to oneself or to others, as well as to understand that others may have different thoughts, affects and intentions than one's own. ToM is essential in our daily lives to understand human behavior and social interactions. It is well established that autistic individuals have difficulties judging others' intentions and emotions in complex social situations due to impairments in ToM. However, most studies that use complex ToM tasks to measure mental state understanding require participants to comprehend verbal stimuli. Although autistic children tend to perform better at non-verbal tasks in general, few studies have investigated the performance of these children on ToM tasks using only non-verbal stimuli.

Objectives: This project investigated (1) whether children with autism (ASD) perform differently than neurotypical (NT) children at a ToM task measuring both moral judgement and *faux pas*; (2) whether intellectual abilities are associated with the performance on this visual task.

Methods: A novel ToM task was used, based solely on visual stimuli (vignettes for the stories and images for the answers), relating to the comprehension of social relationships. Twenty-eight children (16NT; 12ASD) completed a ToM task by exploring visual stories about moral judgements and *faux pas*. The task consisted of six moral scenarios, which differed in the nature of the action portrayed by the characters: accidental or intentional. The scores were calculated by adding up the correct answers for each item of the moral judgements and *faux pas* separately, and together. IQ was measured using the Wechsler abbreviated scale of intelligence.

Results: Both groups were closely matched in age (p=.208) and IQ (p=.196) (Table 1). Autistic children performed as well as the NT children at the ToM task in general (t(26)=-1.048; p=.304). Furthermore, there was no difference between groups in their moral judgement (t(26)=-.517; p=609) and *faux pas* abilities (t(15.78)=-1.088; p=293). In the autistic group, the performance on the ToM task was not significantly associated with global IQ, verbal IQ, nor performance IQ, all ps > .05. However, in the NT group, task performance was positively and significantly correlated with global IQ (r=.586, p<.05) and performance IQ (r=.568, p<.05).

Conclusions: This study examined the performance differences on a ToM task using visual scenarios related to morality and *faux pas* between an autistic and NT group. This study also investigated the relationship between performance on the task and intellectual level. The results indicate that autistic and NT children performed equally well on the ToM task when presented visually (no verbal replies were required). Additionally, the intellectual level was associated with the performance on the task in the NT group, but not in the autistic group. These results support the idea that 1) individuals with autism are predominantly visual rather than verbal, and 2) due to this particular cognitive style, autistic children may benefit from having access to visual elements during problem-solving tasks about social situations, regardless of their intellectual level.

232 **169.232** Unique Social Cognitive Profiles in Autism and Fragile X Syndrome: Influences on Pragmatic Language

L. Bush[1], *G. E. Martin*[2] *and M. Losh*[3], *(1)Northwestern Feinberg School of Medicine, Chicago, IL, (2)Communication Sciences and Disorders, St. John's University, Staten Island, NY, (3)Communication Sciences and Disorders, Northwestern University, Evanston, IL*

Background: Social cognition refers to the ability to infer thoughts and emotions in others and includes skills such as intentionality, perspective-taking, and false belief understanding. Social cognition is impaired in ASD, and has been implicated in the pragmatic impairments that define ASD. Social cognitive impairments have also been documented in fragile X syndrome with co-occuring ASD (FXS-ASD), and similarly appear related to this group's pragmatic language deficits (Losh et al., 2012). Importantly, the majority of past work has tended to analyze summary scores or single instruments of social cognition, which do not capture different types of social cognitive skills and their discrete impact on pragmatic language.
Objectives: This study used a series of social cognitive tasks ranging in difficulty (appropriate for age ranges in typical development from ~18 months-5 years) to compare social cognitive profiles across groups and examine the impact of these differences on pragmatic language in ASD and FXS-ASD.

Methods: Participants included children with ASD (29 boys) and FXS-ASD (46 boys, 15 girls). To determine the specificity of social cognitive patterns to ASD (idiopathic and syndromic), children with FXS only (13 boys, 27 girls), Down syndrome (20 boys, 22 girls), and typical development (19 boys, 18 girls) were also included. Tasks of perspective-taking (Slaughter et al., 2007) and 1st order false belief (Matthews et al., 2003; Lewis and Mitchell, 1994) were administered. Pragmatic language was assessed from language samples obtained through the Autism Diagnostic Observation Schedule (ADOS; Lord, 2001) and analyzed with a detailed hand-coding system for contingent (on-topic) and perseverative (repetitive) language, which prior research has identified as areas of overlap between ASD and FXS-ASD (Martin et al., in prep; Roberts et al., 2007; Tager-Flusberg & Anderson, 1991).

Results: Individuals with ASD and FXS-ASD demonstrated a marked pattern of social cognitive performance in which they passed the 1st order false belief task but failed the perspective-taking task. This pattern was very rarely observed in any of the other groups, and differentiated ASD and FXS-ASD from all other groups with 98% specificity. Participants with ASD and FXS-ASD who showed this pattern were also more perseverative and noncontingent in conversation than those who did not (ps<.05). Less contingent language in ASD and FXS-ASD, as well as more perseveration in FXS-ASD, were observed in those who failed the perspective-taking task compared to those who passed (ps<.05). Boys with ASD and FXS-ASD who failed false belief were more perseverative and less contingent, respectively, than those who passed (ps<.05).

Conclusions: A distinct pattern of social cognitive impairment was observed in both idiopathic and syndromic ASD, where children passed more advanced false belief tasks while failing a more basic task of perspective-taking. This pattern was generally not observed in the three other groups. This unique pattern of social cognitive difficulty also predicted shared pragmatic language impairments in individuals with ASD and FXS-ASD. Together, these data may help to define the role of social cognition in pragmatic language in ASD.

233 **169.233** Using Eye-Tracking to Investigate Social Information Processing (SIP) in Autism Spectrum Disorders (ASD)

S. M. Francis[1], *D. Srishyla*[1], *D. Back*[2], *K. Dalrymple*[3], *M. Manner*[4], *J. T. Elison*[5] *and S. Jacob*[1], *(1)Department of Psychiatry, University of Minnesota, Minneapolis, MN, (2)Medical School, University of Minnesota, Minneapolis, MN, (3)Institute of Child Development, University of Minnesota, Minneapolis, MN, (4)Department of Computer Science and Engineering, University of Minnesota, Minneapolis, MN, (5)University of Minnesota, Minneapolis, MN*

Background: A common characteristic of autism spectrum disorder (ASD) is deficits in social information processing. For effective interactions and communication, it is crucial to assess socio-emotional information from faces and to correctly interpret facial expressions in real-time. Tracking an individual's eye movements as they view a facial expression can offer insight into how an individual is processing relevant information. Using eye-tracking, we can measure location and duration of gaze, which allows us to assess subcomponents of social information processing in individuals.
Objectives: This study investigated differences in accuracy of emotion identification and eye-tracking metrics (locations and durations) during the Dynamic Affect Recognition Evaluation task (DARE; Bal et al, 2010; affects: happy, sad, anger, fear, surprise, disgust) in both individuals with and without ASD.

Methods: Two groups of participants were recruited to perform DARE. Fifteen individuals (mean age: 13.64±2.33y; IQ>70) diagnosed with ASD (ADOS and most had ADI-R) and 19 individuals (mean age: 12.74±1.97y) without diagnoses. To examine differences in accuracy, trial duration, and fixation between and within groups, different size ANOVAs (5x2, 1x6, and 3x2) followed by post hoc analysis with corrections were performed. Kendall's tau-b was used to note correlations between accuracy and eye metrics.

Results: Preliminary results suggest that ASD versus control differences (between group analysis) in accuracy of emotion recognition during adolescence are not significant. Significant differences in trial duration between the groups were observed. Individuals with ASD had longer trial durations for happy, surprise, fear, and anger (all: $p<0.001$) as compared to controls. Examining the eye-tracking data, we noted that controls on average had longer fixation durations on areas of interest (AOIs) in comparison to the ASD group across all emotions (all: $p<0.001$).

Within group analysis noted a negative correlation between accuracy on disgust and fixation duration on the mouth ($\tau b= -0.579$, $p=0.009$) in the ASD group. Analysis also yielded significant differences in accuracy between: happy > anger ($p=0.005$), happy > disgust ($p=0.002$), surprise > anger ($p=0.038$), and surprise > disgust ($p=0.014$). Within the group, trial duration was significantly shorter for happy versus anger ($p=0.009$). This group also had a longer mean fixation duration on the eyes in disgust versus happy ($p=0.029$). Analysis within the control group yielded a significant difference in accuracy, happy > fear ($p=0.016$). Trial duration did not significantly differ between emotions in the control group.

Conclusions: While there were no significant differences between groups in the accuracy of identifying emotion, there were differences in the strategies between the groups – where individuals looked (location) and for how long (duration). This suggests that by adolescence individuals with ASD establish a strategy that may be different from non-ASD individuals, but still allows for accurate emotion recognition. Going forward, we will increase sample size to ensure that the results are robust, examine eye movements between AOIs by analyzing frequency of saccades, and investigate the effect of age on task strategy.

234 **169.234** Viewing of Social and Non-Social Information in Natural Scenes in High-Functioning Adults with ASD

S. Skripkauskaite[1]*, J. Mayer*[2] *and L. Slade*[3]*, (1)University of Roehampton, London, United Kingdom of Great Britain and Northern Ireland, (2)University of Roehampton, London, United Kingdom, (3)Canterbury Christ Church University, Canterbury, United Kingdom*

Background: Research has suggested that individuals with autism spectrum disorders (ASD) exhibit less attentional engagement with social information than typical (e.g. Klin, Jones, Schultz, Volkmar, & Cohen, 2002), yet not consistently so. Thus, it remains unclear what the underlying mechanisms determining the presence of atypical social viewing in ASD are. Recently, it has been proposed that the content of the scene and the nature of the competing non-social information may moderate the reduced attention to social information seen in individuals with ASD (e.g. Chita-Tegmark, 2016).

Objectives: The primary aim of the current study was to evaluate whether high-functioning adults with ASD exhibited atypical attentional engagement with social and non-social information in naturalistic scenes. Secondly, the current study aimed to examine whether social content (i.e. number of people depicted) of the scene and/or subjective relevance (high and low) of the information within the scene as classified by independent judges may be explaining atypical social attention in ASD.

Methods: The sample consisted of 24 high-functioning adults with ASD and 26 age and IQ matched typically developed (TD) adults. Photographs of 24 naturalistic scenes depicting either low (1 - 4 people) or high (6 - 12 people) social content were used. Participants' gaze behaviour (i.e. visit durations) data was collected using eye-tracking and analysed using multi-level modelling.

Results: Participants with ASD viewed social information and subjectively relevant areas of the scene less than TD adults. However, increased social content affected adults with ASD similarly to TD adults by reducing their attention to the scene overall, to the subjectively more relevant areas, and to the social information in particular.

Conclusions: These findings suggest that the reduced social attention in ASD occurs due to the lack of social bias seen in TD adults rather than the non-social bias. Furthermore, it provides empirical support for the atypical prioritisation of perceived information in ASD by showing that adults with ASD pay less attention to the information judged as relevant by TD adults.

235 **169.235** Visual Attention to Cute Stimuli in Children with Autism Spectrum Disorder (ASD): An Eye-Tracking Study

A. Zaharia[1]*, M. Schaer*[2]*, T. Rojanawisut*[1]*, N. Kojovic*[3]*, D. Sander*[1] *and A. C. Samson*[1,4]*, (1)Swiss Center for Affective Sciences, University of Geneva, Geneva, Switzerland, (2)Developmental Imaging and Psychopathology Lab, University of Geneva, Geneva, Switzerland, (3)Developmental Imaging and Psychopathology Lab, UNIGE, Geneva, Switzerland, (4)Department of Psychiatry and Behavioral Science, Stanford University School of Medicine, Stanford, CA*

Background: Previously, research showed that individuals with ASD present an atypical pattern of positive emotional experience, as for instance: lower levels and a smaller range of positive emotions, as well as less positive facial expressions. A strong trigger to induce positive emotions in typical development (TD) is the baby schema, which consists of infantile physical features perceived as cute (e.g., big eyes, small mouth). These features also activate caretaking behavior, affiliation and social interaction.

Objectives: Our study aimed at investigating the sensitivity towards the baby schema in children with ASD and TD children. We explored the eye gaze responses to stimuli with strong (infants, animals) and less strong (adults) cute features in individuals with ASD compared to TD individuals. We also expected that sensitivity towards the baby schema would be linked to social impairments.

Methods: Fifteen children with ASD (M_{age}=5.47, SD_{age} = 1.96, 14 males) and 12 TD children (M_{age}=5.42, SD_{age} = 1.43, 7 males) participated in the study. Using eye-tracking technology (Tobii TX300), we compared the eye gaze patterns (time spent and number of fixations on areas of interest) during a visual exploration task in two conditions: frames that portrayed (1) infants, animals, and neutral objects, or (2) adults, animals, and neutral objects. Stimuli depicting animals and infants obtained similar cuteness ratings and were rated cuter than stimuli depicting adults during stimuli validation stage. Additionally, we assessed social impairment severity using Social Responsiveness Scale-2 (SRS-2).

Results: Repeated-measures ANOVAs revealed that participants with ASD show fewer fixations on animals compared to TD participants in both conditions. In addition, they showed a different eye gaze pattern in exploring frame (2): children with ASD spend less time on animals, but more time on adults compared to TD participants. Moreover, we computed a Cuteness Sensitivity Index (CSI) as a measure of sensitivity to focusing on infants versus adults, for which a low value indicates more time spent on infants and a high value indicates more time spent on adults. A positive correlation between the CSI and severity of social impairments was only found in the TD group.

Conclusions: These preliminary results suggest a decreased sensitivity towards the cute features in participants with ASD compared to TD.

Specifically, children with ASD compared to TD participants, seem to be less attracted to cute stimuli representing animals and more attracted to less cute stimuli representing adults during a visual exploration task. Moreover, our results showed that TD participants who spend more time on infants show less social impairments. This may suggest that sensitivity to cuteness has the potential to facilitate social interactions and predict better social outcomes. Future studies should test the relevancy of these findings in longitudinal studies to examine the predictive value of the sensitivity towards cuteness for socio-emotional development in individuals with ASD.

236 **169.236** “Thin-Slicing” Everyday Conversations: A Quick, Low-Cost Way to Add New Dimensionality to ASD Conceptualization

L. Bateman[1]*, E. F. Ferguson*[1]*, M. Cola*[2]*, S. Uh*[2]*, S. Plate*[2]*, Z. M. Dravis*[2]*, A. Pomykacz*[3]*, K. Bassanello*[2]*, A. Zoltowski*[4]*, J. D. Herrington*[5]*, K. Bartley*[5]*, E. S. Kim*[2]*, A. de Marchena*[6]*, J. Pandey*[2]*, R. T. Schultz*[2] *and J. Parish-Morris*[2]*, (1)The Center for Autism Research/CHOP, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Children's Hospital of Philadelphia- Center for Autism Research, Philadelphia, PA, (4)Vanderbilt University, Nashville, TN, (5)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (6)University of the Sciences, Philadelphia, PA*

Background: Individuals with autism spectrum disorder (ASD) are characterized by social communication challenges and repetitive behaviors that may be perceived differently by new acquaintances than by parents or expert clinicians. Intriguingly, recent research suggests that even naïve non-experts are capable of forming accurate impressions about a variety of human dimensions using only narrow windows of experience called “thin-slices” (Slepian, Bogart, & Ambady, 2014). In this study, we explore “thin-slice” ratings of interaction quality in ASD and typical controls after a 5-minute conversation.

Objectives: First, compare “thin-slice” ratings between participants with ASD and typical development (TD). Second, compare “thin-slice” ratings of participants with ASD to scores from a parent questionnaire (SCQ) and expert clinical observation (ADOS). We hypothesized that since parent questionnaire scores are based on a lifetime of experience, and ADOS scores are based on a shorter (~1 hour) interaction, that 5-minute “thin-slice” ratings would more closely resemble ADOS scores than SCQ scores, despite the non-expert status of the rater.

Methods: Forty-five participants with ASD (N=28; 8 female) or typical development (TD; N=17; 13 female) completed a ~5 minute unstructured “get-to-know-you” session with a novel conversational partner (N=14, 11 female). Participant groups did not differ significantly on age (11.75 years) or IQ (106), but the TD group had more female participants than the ASD group (imbalance will be corrected by May, 2018). After each conversation, conversational partners completed a modified version of the Conversation Rating Scale (CRS; Ratto et al., 2011). The original CRS included 5 questions indexing conversational interest, warmth, flow, boredom, and distance on a 1 (strongly agree) to 7 (strongly disagree) Likert scale. A sixth question about appropriate eye contact was added for the purposes of this study.

Results: Linear mixed effects regression models with conversational partner as a random effect revealed that the ASD group received lower overall CRS scores than the TD group, and were perceived as significantly less warm and more distant, with less appropriate eye contact (*p*s<.01, Fig.1). There were no significant group differences in perceived boredom, interest, or conversational flow. Warmth, distance, and eye contact scores were combined into a 3-item CRS composite that was found to correlate with ADOS severity scores in the ASD group ($r=-.62$, $p<.001$), but not with SCQ scores (Fig.2).

Conclusions: “Thin-slice” ratings of naturalistic conversations hold promise as a low-cost metric to gauge the impression that individuals with ASD make on naïve communication partners in everyday life. In this study, we identified three questions about a 5-minute conversation with a naïve interlocutor that differentiated diagnostic groups, and accounted for nearly 40% of the variance in ADOS scores of participants with ASD. The CRS 3-item did not correlate with SCQ scores, suggesting that “thin-slice” ratings capture variance that is orthogonal to parent perceptions of autism symptoms. We propose that non-expert “thin-slice” ratings provide a more complete and nuanced picture of ASD in daily contexts, adding new dimensionality to our conceptualization of the disorder.

237 **169.237** "I Wish I'd Know That When I Was Younger" - a Qualitative Exploration of the Change over Time in the Relationships of Autistic Girls and Women from Multiple Perspectives

F. R. Sedgewick[1]*, E. Pellicano*[2] *and V. C. Hill*[3]*, (1)Centre for Research in Autism and Education (CRAE), London, United Kingdom of Great Britain and Northern Ireland, (2)Macquarie University, Sydney, Australia, (3)Psychology and Human Development, UCL Institute of Education, London, United Kingdom*

Background:

While there is growing interest in the experiences of girls and women on the autism spectrum, no published work has yet examined how their relationships change between two key developmental stages, adolescence and early to mid-adulthood – both of which are characterised by significant changes in social experiences and expectations.

Objectives:

This cross-sectional study sought to examine the friendship and romantic experiences of two distinct cohorts of autistic females, adolescent girls and adult women, to elucidate potential similarities and differences across these distinct stages of development. Parental views were also sought to provide multi-informant perspectives on girl’s experiences.

Methods:

We conducted semi-structured interviews with 27 autistic girls (M age:14 years 5 months) and 19 autistic women (M age:30 years 2 months) about their relationships and conflict experiences. 20 of 27 parents of autistic girls were also interviewed about their daughter’s relationships and their thoughts about the future.

Results: Interviews were transcribed verbatim and analysed using thematic analysis. Almost all autistic girls and women discussed having one or more secure relationships, although some described difficulties with maintaining relationships. There were two key commonalities across autistic girls and women’s interviews. First, both autistic girls and women discussed having a few, intense relationships, both as their preference and because they found it “hard work” to maintain more. For autistic girls, this generally took the form of one or two best-friends, without wider social groups. For autistic women, their romantic partner had often taken on this role. Second, both autistic girls and women faced the same type of conflict regardless of life-stage, which was almost exclusively relational in nature. We also identified two key differences between the groups. First, there were notable differences in how autistic girls and women managed conflict they experienced. Autistic girls took a ‘black-and-white’ approach, either entirely assuming blame or seeing an insurmountable problem. In contrast, autistic women had learned to negotiate resolutions, but were also happy to walk away from situations which were too difficult. Second, these changes to conflict management, along with better self-knowledge through the diagnostic process, meant that autistic women were more satisfied with, less anxious about, and more self-assured in their relationships than autistic girls. Finally, one major concern identified from the accounts of autistic women and parents related to vulnerability. Adult women discussed experiencing physical and sexual violence, along with mental health issues. Parents were also concerned about their daughter's vulnerabilities, often actively trying to pre-empt them. Autistic women described how this input would have been useful when they were younger.

Conclusions:

Many of the social experiences reported by adolescent autistic girls were also reported by adult autistic women, including the patterns of their friendships and relationships, and the conflict they face with their peers. There are also apparent improvements in their relationships over time – in conflict management and social satisfaction – despite a range of challenges also present in adulthood. Future work should seek to examine which factors support these relationship improvements, and how these skills could be taught to autistic girls.

238 **169.238** Alexithymia Mediates Facial Muscle Mimicry of Observed Pain in Autism

ABSTRACT WITHDRAWN

Background: Poor empathy and deficits in mimicry of others' emotions have been reported in autism spectrum disorder (ASD). However, studies have either examined only cognitive aspects of empathy or only measured self-reported empathy. Furthermore, most studies have not adequately controlled for cognitive factors influencing empathy expression such as alexithymia; that is, the inability to express or understand one's own emotions.

Objectives: This study was the first to measure involuntary facial mimicry of painful expressions as an indicator of empathy in ASD. Muscle reactivity was examined in individuals with varying levels of autism traits. We hypothesised that muscle mimicry and subjective affective empathy are strongly correlated with alexithymia, but are not impaired in ASD once alexithymia has been controlled for. We further hypothesised that the ability to understand others' emotions, i.e. cognitive empathy, would enhance affective responses.

Methods: The relationship of cognitive empathy and alexithymia to muscle reactivity and subjective affective responses to pain were examined. In total, 98 individuals participated (27 ASD; 79 Male; ages 14 – 46). Participants were shown videos of painful facial expressions lasting 5s each, during which activity in the facial muscles associated with pain (verum; M. orbicularis oculi, M. zygomaticus major) and surprise (control; M. medial frontalis) were recorded using bipolar surface electromyography. Affective state and perceived pain was rated on a 7-point scale after completion of the videos. Autism traits were calculated from observed and self-reported autism behaviours using the Autism Diagnostic Observation Schedule 2 and the Autism Spectrum Quotient. Alexithymia was measured on the Toronto Alexithymia Scale (TAS-20) and cognitive empathy was measured using the Faux Pas task. Affective states, perceived pain and muscle reactivity were predicted from autism traits, alexithymia and cognitive empathy in separate mixed effect models.

Results: Muscle activity increased significantly from the start of the video to the time of greatest pain and was greater in muscles associated with pain than muscles associated with surprise. High trait autism was correlated with lower muscle amplitude, reduced perceived pain intensity and lower subjective affective ratings while observing pain. However, once alexithymia was controlled for, autism traits were no longer correlated with muscle amplitude or affective states. Furthermore, there were no differences in habituation or speed of muscle response between low and high autism trait participants. Cognitive empathy did not predict muscle reactivity or affective responses.

Conclusions: Alexithymia mediates the relationship between autism traits and affective empathy and muscle mimicry. Interestingly, though affective responses to perceived pain are unimpaired in those without alexithymia, participants with high autism traits may report perceived pain as less intense than those with low autism traits. Of note, complex cognitive empathy does not seem necessary for an affective empathic response to perceiving another's pain. These results support theories of separate cognitive and affective neural pathways for empathy.

239 **169.239** Do Children with Autism Spectrum Disorder Share Fairly and Reciprocally?

C. Hartley *and S. G. Fisher, Lancaster University, Lancaster, United Kingdom*

Background:

Sharing is a crucial foundation of human evolution. The conflict between retaining valued commodities and sharing with others is conventionally assessed via resource-exchange tasks, such as the Ultimatum Game (UG) and Dictator Game (DG). In these tasks, typically developing (TD) children and adults demonstrate preferences for equality and reciprocity, and reject incoming offers they perceive to be unfair. As these behaviours are driven by sensitivity to social norms and awareness of others' perspectives, there may be significant differences in how children with autism spectrum disorder (ASD) share with others. Importantly, failure to share fairly and reciprocally could impact children's ability to build friendships and increase their risk of bullying.

Objectives:

The objective of this study was to explore how children with ASD and TD children share stickers in age-appropriate versions of the UG and DG. In the ASD group, we expected to observe a weaker preference for equality, reduced reciprocity, and fewer verbal references to fairness.

Methods:

Participants were 15 children with ASD (*M* age: 9.2 years) and 18 TD children (*M* age: 4.3 years) matched on language comprehension (ASD *M* age: 5.1 years; TD *M* age: 4.83 years). On different days, children played the UG and DG with a puppet. Each game involved two roles: proposer and recipient (players alternated roles for 4 turns). The proposer received 8 stickers and decided how many to offer the recipient. In the UG, the recipient could accept or reject the proposer's offer. In the DG, the recipient always accepted the proposer's offer. In each game, the puppet made one fair offer (4 stickers) and one unfair offer (1 sticker) in a random order, and their responses were randomised in the UG.

Results:

Both groups indicated a preference for equality over self-interest in the UG (ASD *M* offer: 3.31; TD *M* offer: 3.39), offered significantly fewer stickers in the less socially-strategic DG (ASD *M* offer: 2.77; TD *M* offer: 2.75; $p = .006$), and explicitly referred to fairness at similar rates when making and receiving offers (*p*s = .17-.64). However, children with ASD were more likely to accept unfair offers than TD children (40% vs 11%; $\chi^2 = 3.77$, $p = .05$) and were less likely to reciprocate the puppet's offers in both games ($p = .04$-07). Strikingly, children with ASD reciprocated fair offers at much lower rates in both the UG (ASD: 56%; TD: 93%) and DG (ASD: 50%; TD: 75%).

Conclusions:

Although both groups exercised an explicit notion of fairness (as indicated by their offers and comments), ASD impacted children's ability to evaluate the fairness of others' offers and to reciprocate accordingly. Crucially, reduced reciprocation of others' fair behaviour by children with ASD could elicit negative affect in peers and lead to marginalisation, while increased tolerance of unfair behaviour could increase their susceptibility to bullying. Due to deficits in social-cognition and interaction, children with ASD might be increasingly motivated by material outcomes (irrespective of whether they are personally disadvantaged), and less concerned about defending norms associated with positive social-relational outcomes.

Oral Session -
Invited, Keynote Speakers, Awards
175 - Welcome Address & Sponsor Update
8:45 AM - 9:00 AM - Grote Zaal

8:45 Welcome Address & Sponsor Update.

Oral Session -
Invited, Keynote Speakers, Awards
176 - Keynote Address - Mark H. Johnson, FBA
9:00 AM - 10:00 AM - Grote Zaal

Professor Mark H. Johnson, FBA is Professor of Experimental Psychology (1931) and Head of the Department of Psychology, Cambridge University, UK. After obtaining a degree in Biology and Psychology from the University of Edinburgh (UK), and a PhD in neuroscience from Cambridge, he held academic and research positions at the MRC Cognitive Development Unit, London (1985-89 and 1994-98), University of Oregon, Eugene (1988-89), and Carnegie Mellon University, Pittsburgh (1990-95), before he moved to become MRC Director of the Centre for Brain & Cognitive Development at Birkbeck, University of London in 1998. He has published over 350 papers and 10 books on brain and cognitive development in humans and other species, including the textbook "Developmental Cognitive Neuroscience" now in its 4th Edition. Currently his laboratory focuses on typical, at-risk and atypical functional brain development in human infants and toddlers using a variety of different neuroimaging, cognitive, behavioural, and genetic methods. Johnson coordinates several national and international collaborative scientific networks, and is a named fellow of the APS, BPS, Cognitive Science Society and British Academy (FBA).

9:00 Babies At-risk for Autism: Assumptions, Progress and Prospects

M. H. Johnson, *Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom*

For over a decade a number of research groups world-wide have studied infants at-risk of autism in order to reveal the early developmental pathway that results in diagnosis. I will discuss the key assumptions that underpin this body of research, and the general approach taken of prospective longitudinal studies. Key conclusions from research so far will be illustrated by selected studies from our group in the UK (BASIS) and a European network (Eurosibs). Despite many findings, however, a number of fundamental issues about the early emergence of autism remain unresolved. I will argue that some of these issues may be resolved if autism is seen as being the result of a common alternative trajectory of human brain development. By this view autism is not a disorder of development, but rather an ordered developmental response to a different starting state.

Panel Session
Social Cognition and Social Behavior
177 - The Autism Biomarkers Consortium for Clinical Trials: Overview and Presentation of Interim Analyses
10:30 AM - 12:30 PM - Grote Zaal

Panel Chair: James McPartland, *Child Study Center, Yale University School of Medicine, New Haven, CT*

Discussant: Declan Murphy, *Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

The Autism Biomarkers Consortium for Clinical Trials (ABC-CT) is a US-based network designed to develop objective measures to more sensitively and validly quantify ASD symptomatology and its change in clinical trials and to stratify ASD into meaningful subgroups. This symposium will present results from ABC-CT interim analyses, when half of the total sample has been evaluated at the second of three time points. This panel brings together six autism research centers, with panelists spanning early career faculty to senior leaders in the field. The first lecture will provide an overview of study design, with focus on progress to date and unique elements of the approach to biomarker development. The second lecture will present clinical data from the interim sample, and the third and fourth lectures will provide preliminary biomarker results obtained from EEG and eye-tracking studies, respectively. The discussion, provided by leadership from EU-AIMS, a collaborating European biomarker consortium, will focus on unique concerns for biomarkers that can facilitate prediction of outcome and diagnostic stratification and on development of large-scale consortia and clinical networks for study of biomarkers in ASD.

10:30 **177.001** The Autism Biomarkers Consortium for Clinical Trials: Study Design and Progress to Interim Analysis

J. McPartland[1]*, S. J. Webb*[2]*, F. Shic*[3]*, A. Naples*[1]*, C. Sugar*[4]*, M. Murias*[5]*, J. Dziura*[6]*, C. Brandt*[6]*, R. Bernier*[2]*, K. Chawarska*[1]*, G. Dawson*[7]*, S. Faja*[8]*, S. Jeste*[4] *and C. A. Nelson*[8]*, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (4)University of California, Los Angeles, Los Angeles, CA, (5)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (6)Yale University, New Haven, CT, (7)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (8)Boston Children's Hospital, Boston, MA*

Background:
Recent scientific advances offer promise for the development of targeted treatment methods to improve social-communication in autism spectrum disorder (ASD). The promise of targeted treatments is hindered by a lack of reliable and sensitive objective measures to identify subgroups likely to respond to specific treatments, to rapidly assess response to treatment, and to evaluate whether a treatment has affected the intended target. The Autism Biomarkers Consortium for Clinical Trials is a multisite biomarker development study designed to advance these objectives.

Objectives:

The goals of the ABC-CT are to: (1) establish sensitive and reliable objective EEG, eye-tracking (ET), and lab-based behavioral assays of social communication in ASD for predicting and quantifying response to treatment, reducing heterogeneity of samples via stratification, indicating early efficacy, and demonstrating target engagement; (2) create a publicly accessible repository spanning genetics, biomarkers, and clinical and behavioral information; and (3) establish an infrastructure optimized for the conduct of future clinical trials.

Methods:

Prior to commencing full-scale data collection, a feasibility study assessed 51 subjects (25 ASD, 26 TD) to ensure: standardization and viability of data collection across sites; valid and reliable implementation of experimental measures; effectiveness of data processing, extraction, and quality control procedures; and reliability of data management, upload, and sharing systems. The main study commenced in October 2016 and will include 200 rigorously characterized children with ASD (6-11 years; IQ 60-150) and 75 typically developing (TD) control subjects at three time points (Baseline, 6 weeks, 24 weeks). Detailed manuals of procedures (MOPs) and identical biomarker acquisition hardware and software are intended to minimize variance in ascertainment across sites, and clinical characterization is standardized with a clinical MOP and regular teleconferences to ensure reliability. A unique study governance brings together diverse expertise to facilitate progress from discovery to biomarker qualification. To provide opportunity for confirming biomarker results in independent samples, several EEG and ET paradigms are harmonized with those utilized in EU-AIMS.

Results:

As of October 2017, 203 participants have been enrolled in the main study, with 181 having reached 6 week visits and 116 having reached 24 week visits. Data acquisition procedures have been highly successful, with valid data acquisition rates above 96% across biomarker data modalities, and longitudinal attrition has been minimal (N=15). Panels in this symposium will report data from the interim analysis sample, at which point approximately half of the main study sample will have completed a 6 week visit. Interim analyses will focus on preliminary evaluation of biomarkers for clinical trials, in terms of acquisition and psychometric properties, as well as utility for stratification, discrimination, and indicating clinical status.

Conclusions:

The ABC-CT, and other consortia like it, are advancing the goal of clinically practicable biomarkers by investigating well-evidenced biomarkers in large, well-characterized cohorts in the context of a longitudinal design. Progress in these studies is laying groundwork for more sensitive and reliable measurement in clinical trials, and the use of economical and scalable biomarker technologies holds promise for eventual deployment in a broader range of clinical and research contexts.

10:55 **177.002** The Autism Biomarkers Consortium for Clinical Trials: Clinical Characteristics and Interim Evaluation of Clinical Measures Commonly Used in Clinical Trials

S. Faja[1]*, R. Bernier*[2]*, G. Dawson*[3]*, K. Chawarska*[4]*, S. Jeste*[5]*, C. A. Nelson*[1]*, S. J. Webb*[2]*, F. Shic*[6]*, A. Naples*[4]*, C. Sugar*[5]*, M. Murias*[7]*, J. Dziura*[8]*, C. Brandt*[8] *and J. McPartland*[4]*, (1)Boston Children's Hospital, Boston, MA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)University of California, Los Angeles, Los Angeles, CA, (6)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (7)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (8)Yale University, New Haven, CT*

Background: The investigation of social interventions for ASD has traditionally relied on clinician rating scales and parent surveys, raising concerns about their relation to underlying mechanisms targeted by treatment, sensitivity to treatment-related changes, and potential for bias when used to measure interventions that are difficult to mask from clinicians and families. The ABC-CT provides an opportunity to examine the utility of these measures with respect to construct test-retest reliability, discriminant and convergent validity. The project also provides an opportunity to examine the feasibility of collecting clinical data in a reliable and precise manner across a five-site consortium.

Objectives: To examine the interim characteristics of a large sample, including possible site-specific differences. To examine convergent validity of the clinical battery, particularly for social communication symptoms of ASD. To explore whether standardized lab-based measures of face and emotion recognition discriminate groups and relate to traditional measures of clinical function. To examine interim data for test-retest validity of commonly used clinical measures.

Methods: To date, data are available from the Feasibility phase of the project, which included 25 children with ASD and 26 typically developing controls (4-11 years, FSIQ = 53-133). The presentation will include data from approximately 205 children across two time points at ABC-CT interim analysis.

Results: There were site specific differences in age, but not gender or clinician rating measures: ADOS-2 calibrated severity scores, ADI-R, Vineland-3, or CGI. In terms of convergent validity within the social domain, clinician ratings of social symptom severity (CGI) related to ADOS-2 social affect calibrated severity scores, Vineland-3 socialization, PDDBI Social Pragmatic, and SRS-2 Social Communication ($ps < .05$), suggesting excellent convergent validity for the CGI with other measures of current social communication symptoms within the group with ASD. The ADI-R social domain, which emphasizes historical symptoms; PDDBI Social Approach; SRS-2 Social Awareness, Social Cognition, Social Motivation; and CASI Autism and Asperger scales were not related to CGI. In contrast, the ADOS-2 social affect calibrated severity score was unrelated to ADI-R social, PDDBI, SRS-2 or CASI scales related to social communication symptoms. Likewise, the ADI-R Social scale was related to only the SRS-2 Social Cognition and Social Motivation and CASI Autism/Asperger's scales. The Vineland-3 Socialization scale related to all CASI, SRS-2 and PDDBI social and autism scales (*ps* <.06), and all SRS-2 and PDDBI social scales were related to each other (*ps* <.05). A standardized lab-based measure of face and emotion recognition (NEPSY-2) discriminated groups (face: $t(40)=5.03$, $p<.001$; emotion: $t(40)=2.75$, $p=.009$) and face memory related the ADOS-2 social affect scores.

Conclusions: Initial findings from ABC-CT feasibility provide information to guide selection of social measures for clinical trials confirming that traditional measures are feasible in a multisite clinical trial, have varying convergent validity, and are relatively independent from performance-based measures, such as the NEPSY-II. The replication of these findings among a larger sample (N=200), including test-retest reliability over a 6-week period will also be presented.

11:20 **177.003** The Autism Biomarkers Consortium for Clinical Trials: EEG Interim Analyses

S. J. Webb[1], *A. Naples*[2], *A. R. Levin*[3], *G. Hellemann*[4], *C. Sugar*[5], *D. Senturk*[4], *M. Santhosh*[6], *H. M. Borland*[7], *T. McAllister*[2], *S. Hasselmo*[2], *F. Shic*[7], *M. Murias*[8], *J. Dziura*[9], *C. Brandt*[9], *R. Bernier*[1], *K. Chawarska*[2], *G. Dawson*[10], *S. Faja*[11], *S. Jeste*[5], *C. A. Nelson*[11] *and J. McPartland*[2], *(1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Neurology, Boston Children's Hospital, Boston, MA, (4)UCLA, Los Angeles, CA, (5)University of California, Los Angeles, Los Angeles, CA, (6)Seattle Children's Research Institute, Seattle, WA, (7)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (8)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (9)Yale University, New Haven, CT, (10)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (11)Boston Children's Hospital, Boston, MA*

Background: Autism Biomarkers Consortium for Clinical Trials (ABC-CT) electroencephalography (EEG) paradigms aim to identify social-communicative brain biomarkers relevant to autism spectrum disorder (ASD), using measures of signal strength (i.e., modulation of EEG spectral power and event-related potential latency/amplitude). Prior to commencing the full scale "main" study data collection (ongoing), a feasibility study was conducted to ensure standardization and viability of data collection across sites and effectiveness of data processing, extraction, and quality control procedures. This is particularly vital for EEG, as there have been few multisite data collection studies or test-retest evaluations, specifically in this age range and including the full functional variability in ASD.
Objectives: To investigate the acquisition validity, test-retest reliability; discriminant validity, and relation to clinical status of EEG measures of social communication in ASD.

Methods: EEG was collected across 51 participants (25 with ASD, 26 typically developing (TD), ages 4-11) over two days counterbalanced by day and within-day experiment order: (A) Resting (or calm viewing), visual evoked potential (VEP; checkerboard), and EU-AIMS Faces (based on the EU-AIMS face experiment), (B) Resting, Biomotion (point light displays of walkers), Dynamic social/nonsocial videos, and Emotion Faces. Equipment (EGI 128-channel EEG system), experimental control, and recording parameters were standardized across sites. Data processing and analyses were conducted via NetStation and Matlab, utilizing automated artifact detection and custom-made programs for component abstraction. Primary dependent variables, selected based on literature review, included slope of the power spectrum (Resting, Dynamic social/nonsocial), which is thought to be a marker of signal:noise ratio within the brain, as well as amplitude and latency of the P1 (VEP) and N170 (Biomotion, Faces, Emotion Faces) components. Validity was defined as valid acquisition (e.g., participant protocol compliance) and artifact free data for >40 seconds or 30% of trials.

Results: During feasibility, validity rates were >90% for Resting, Dynamic, VEP, and EU-AIMS Faces, and >80% for Biomotion and Emotion Faces. Significant differences (ps<.05) were found for Group for Resting slope (t=9.4). Effects of age were identified in Resting slope (t=4.1), Emotion Faces N170 latency (t=5.2), and VEP P1 amplitude (t=2.9). Interactions were found for diagnosis by age for Faces N170 amplitude (t=1.7), and diagnosis by verbal IQ for Emotion N170 amplitude (t=5.2) and VEP P1 amplitude (t=2.7). This symposium will present updated data from interim analyses, which includes Ns>175 of the main study sample and includes Resting, VEP, Faces (modified from feasibility), and Biomotion. Current Main Study (baseline) rates of acquisition are 97.5% valid session acquisition with valid derived results between 81% and 94% by experiment.

Conclusions: EEG measures showed high levels of data retention across site, age, and diagnostic categories. Biomarkers were highly sensitive to age and showed high levels of construct validity. Interim analyses data will provide additional information regarding EEG biomarker performance in feasibility and main study, test-retest stability, and implications for identifying an EEG biomarker with suitable psychometric performance, relation to clinical status, and potential for stratification in future clinical trials.

11:45 **177.004** The Autism Biomarkers Consortium for Clinical Trials: Eye Tracking Interim Analyses

F. Shic[1], *A. Naples*[2], *E. Barney*[1], *C. Sugar*[3], *M. Murias*[4], *J. Dziura*[5], *C. Brandt*[5], *R. Bernier*[6], *K. Chawarska*[2], *G. Dawson*[7], *S. Faja*[8], *S. Jeste*[3], *C. A. Nelson*[8], *S. J. Webb*[6] *and J. McPartland*[2], *(1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)University of California, Los Angeles, Los Angeles, CA, (4)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (5)Yale University, New Haven, CT, (6)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (7)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (8)Boston Children's Hospital, Boston, MA*

Background:
Eye tracking (ET) provides indices of cognitive processes via overt attention. ET measures robustly capture differences in social information processing in ASD, as well as associations with clinically-relevant phenotype. However, many prior studies have focused on theoretical mechanisms, relied on small samples, or have not been replicated.

Objectives:
To examine the suitability of several prominent ET paradigms for use as autism biomarkers.

Methods:

ET data were acquired from 4-11 year-old (average: 7.2±2.2 years) children with ASD (*n*=24) and typical development (TD, *n*=26) with EyeLink 1000 Plus 500hz eye trackers during the following experiments: activity monitoring (AM: actresses engaged in shared activities), social interactive (SI: play interaction between children), biological motion (BM: side-by-side presentations of human motion point-light versus scrambled/rotating points), dynamic naturalistic scenes (DNS: social/emotional movies), visual search (VS: array of social/non-social objects), gap overlap (GO: orienting to a peripheral target from a central cue), pupillary light reflex (PLR: pupil size changes after bright flash), static scenes (SS: naturalistic social scenes), and spontaneous social orienting (SSO: actress looking and speaking to the camera). IQ was added as a covariate in group comparisons. Trial-level quality control (QC) requirements included: valid data acquired for more than 50% of stimulus presentation (%Valid), calibration uncertainty/error less than 2.5 degrees; experiment-level QC included 25% of trials being valid; subject-level QC included 1 or more valid experiments. Primary and secondary variables varied per experiment. Phenotypic associations were examined in the ASD group using Spearman's rank correlation.

Results:

Valid experiment acquisition was >90% in both groups for all experiments except GO (88%). 96% of the ASD group and 100% of TD provided at least one valid experiment. Lower %Valid was noted in ASD (p<.05) for DNS, PLR, SS, but also in sub-conditions of specific experiments (e.g. static images in AM). No between-group calibration differences emerged for any experiment. Primary variable differences (ASD<TD, *p<.05, ~p<.10) were noted in AM (%Heads*), SI (%Social~), VS (%Face*), SS (%Face*), and SSO (%Face*, Dyadic Bid and Joint Attention phases); secondary differences in DNS (%Eyes*), GO (overall reaction time*); no differences in BM and PLR. Positive associations in ASD were seen between %Valid and Overall IQ (AM~, SI*, VS*), Vineland Social standard scores and SI %Head~, ADOS overall severity and PLR latency~, and age and PLR constriction*; negative associations between IQ and calibration error (AM*,BM*,VS~), ADOS SA severity and %Valid (SS~,VS*), and SRS Social Awareness T and %Heads/%Face (AM*,SI~,SS*). The presentation will include updated data from the larger interim analysis sample.

Conclusions:

ET paradigms generated valid data for nearly all participants. Paradigms with support for validation were mainly drawn from those with primary predictions of diminished face/head looking in ASD. Over multiple paradigms, decreased valid data collection in ASD was associated with lower IQ and increased symptom severity, suggesting QC variables may index pervasive characteristics of atypical attention in ASD. Complex patterns of phenotypic association point to nuances relating to selection of ET paradigms with ideal biomarker characteristics. In summary, these results highlight the promise of ET biomarkers for ASD.

Panel Session
Social Cognition and Social Behavior

178 - Fluctuations over Time in Parenting and Parent-Child Interactions in Families with a Child with Autism Spectrum Disorder

10:30 AM - 12:30 PM - Willem Burger Zaal

Panel Chair: Herbert Roeyers, *Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Discussant: Ilse Noens, *Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium, Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium*

Parent-child interactions influence the emotional, behavioural and cognitive development of children. There is increasing evidence that parent-child interactions and parenting practices are atypical in families with a child with autism spectrum disorder (ASD), but many of the findings lack consistency. This is partly due to the cross-sectional nature of the majority of studies that do not take into account bidirectional and transactional processes occuring in these families. The current panel presents four studies that used different methods to study changes in parenting behaviour and parent-child interactions in infancy, toddlerhood and middle childhood. The first presentation reports findings of a study on dyadic visual attention during parent-child interactions in high-risk (HR) and low-risk (LR) infants at 10 and 14 months. The next presentation focuses on changes in parent-child interactions between 5 and 10 months in a European cohort of HR and LR dyads. The third presentation highlights the changes in parent-child interaction in HR and LR children at five time points between 5 and 36 months. The last presentation reports on a 7-day diary study which analyzed daily parenting fluctuations in mothers of children with ASD. Together the four contributions reflect the dynamic, rather than the fixed, nature of parent-child interactions.

10:30 **178.001** Dyadic Visual Attention during Interactions of Infant Siblings and Their Parents in Relation to the Child's Attention Disengagement and Clinical Symptoms

A. Radkowska[1], *A. Niedzwiecka*[2], *S. Ramotowska*[3], *A. Malinowska*[3], *R. Kawa*[3], *E. Pisula*[3] *and P. Tomalski*[4], *(1)University of Warsaw, Faculty of Psychology, Warsaw, Poland, (2)Health and Rehabilitation Psychology Unit, University of Warsaw, Faculty of Psychology, Warsaw, Poland, (3)University of Warsaw, Warsaw, Poland, (4)Psychology, University of Warsaw, Warsaw, Poland*

Background:

Recently, efforts have been made to investigate the early precursors of autism spectrum disorder (ASD) by studying infants at familial risk for autism (HR). Studying early parent-infant interactions may give insight into the development of this disorder (Wallace & Rogers, 2010). Studies of global characteristics of parent-infant interactions of infant siblings showed that the quality of early dyadic interactions is associated with later diagnostic outcomes in ASD (Wan et al. 2012,2013).

Early development of infant visual attention during social interactions is associated with a range of developmental outcomes in typical and atypical populations. In typical development, dyadic infant-mother mutual attention during free play predicts later efficiency of attention disengagement (Niedźwiecka et al. 2015). HR Infants at 14 months of age differ from low-risk (LR) controls in attention disengagement skills, which predicts subsequent ASD diagnosis at 36 months (Elsabbagh et al., 2013).

Objectives:

This study examined the changes between individual and dyadic visual attention behavior during parent-infant interaction in HR and LR groups, when infants were 10, 14 and 24 months. The following analyses investigated the associations between dyadic states of attention at 10, 14 and 24 months and both concurrent and subsequent attention disengagement and clinical symptoms.

Methods:

As a part of a longitudinal Polish Autism Study of Infant Siblings we analyzed 6-min-long episodes of free parent-infant interactions when infants were 10, 14 and 24 months and coded them in terms of visual attention distribution, (32 HR siblings, 22 LR siblings). We measured the efficiency of attention disengagement using the gap-and-overlap-task and autism symptoms with ADOS-2 at 14, 24 and 36 months. At the conference, we will present the complete dataset including the analysis of visual attention during interactions at 24 months and clinical outcomes at 36 months.

Results:

Although we expected a decrease in the infant attentiveness to the parent in the HR group between 10 and 14 months (Wan et al., 2013), we did not find it in our sample. At both visits at 10 and 14 months HR infants spent more time looking at the parent manipulating an object and less time looking at the parent and at objects alone in comparison to LR siblings. Parents of HR infants spent less time looking at them than parents of LR children at both time points.

Looking at dyadic level of behaviors, we did not find significant group differences in dyadic attention at 10 and 14 months of age. However, dyadic mutual as well as parallel attention during interactions at 10 months were negatively correlated with ADOS-2 scores at 24 months. Additionally, in the HR group, the time spent in mutual attention during interaction at 10 months correlated negatively with results in attention disengagement task at 14 months.

Conclusions:

Dyadic measures of visual attention during infant-parent interactions already at 10 months may constitute an early predictor of later outcomes in HR siblings. Our results suggest the crucial role of the early social interactive environment for visual attention development in atypically developing children.

10:55 **178.002** A Behavioural Profile of Parent-Child Interaction Characteristics during the First Year of Life in High- and Low-Risk Infants

M. K. J. Pijl[1,2], *C. Bontinck*[3], *N. N. J. Rommelse*[4], *S. Kalwarowsky*[5], *E. Cauvet*[6], *A. Niedzwiecka*[7], *T. Falck-Ytter*[8], *E. J. Jones*[9], *T. Charman*[10], *P. Warreyn*[11], *H. Background: During the first year of life the interaction between parent and child forms a key aspect of child's social environment. Previous studies found that parent-child interaction (PCI) in children at high risk (HR) of autism spectrum disorder (ASD) is disrupted. This may be due to either parent or child behaviors that in an interaction between the child's risk status and the social environment leads to an increasingly atypical development. More knowledge is needed about how early PCI differences arise in ASD and how they change over time. Answering these questions may help to strengthen PCI as a promising avenue for early intervention.

Objectives: (1) Investigating the inter-rater reliability of a newly developed coding scheme to rate PCI at 5 and 10 months of age; (2) Obtaining a detailed behavioural profile of the interaction between HR and LR infants and their caregiver, and to investigate differences between these groups.

Methods: As part of the Eurosibs Autism Research network (www.eurosibs.eu), the Parent-Infant/Toddler Coding of Interaction (PInTCI) was developed, including characteristics of PCI that predicted subsequent child development in ASD research. This global coding scheme consists of 5 child constructs (attentiveness – initiations – sharing of affect – positive affect – negative affect), 5 parent constructs (sensitive responsiveness – negative control – scaffolding – positive affect – negative affect) and 1 dyadic construct (dyadic reciprocity), rated on a 1-7 scale. Videotaped parent-child dyads were observed at 5 months (63 HR, 47 LR) and 10 months (93 HR, 73 LR). Coders were blind to risk status.

Results: (1) Intra-class correlations (ICC) showed excellent inter-rater reliability for all PCI constructs at 10 months (ICCs ranged from 0.79 to 0.96, all $p \leq 0.001$). At 5 months, reliability ranged from good to excellent reliability (ICCs ranged from 0.68 to 0.95, all $p < 0.05$), except for a poor to fair reliability for infant initiations (ICC=0.47, $p > 0.05$) and parental negative affect (ICC=0.23, $p > 0.05$) (which were removed from further analyses). (2) Analyses adjusted for age, sex and site showed no differences at 5 months between HR and LR dyads (all $p > 0.05$). At 10 months, results revealed that HR siblings showed less initiations towards their parents as compared to LR siblings ($p < 0.01$). Differences in parent or dyadic behaviors were not found at 10 months (all $p > 0.05$). Examination of PCI characteristics across 5 and 10 months showed no significant effects of time (all $p > 0.05$).

Conclusions: Our results indicate that the PInTCI, based on its inter-rater reliability, seems to be a promising coding measure of PCI that can be used during the first year of life. Application of the PInTCI showed that HR and LR dyads did not differ at 5 months of age, but by the end of the first year dyads started to differ based on the child's behaviour. Consistent with previous literature, our findings suggest that atypicalities start to emerge around the first birthday. Explanations for findings and recommendations for future research will be discussed.

11:20 **178.003** Mother-Child Interaction of High-Risk Siblings throughout the First Three Years of Life

E. Demurie[1], *E. Bruyneel*[2], *J. Vermeirsch*[1], *C. Bontinck*[2], *P. Warreyn*[1] *and H. Roeyers*[1], *(1)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Gent, Belgium*

Background: In families with a child with autism spectrum disorder (ASD), parent-child interactions (PCI) can be more challenging compared to families with only typically developing children. Within the transactional model of development this difference is explained by bidirectional influences of both interaction partners during PCI: parents might try to compensate for their child's social-communicative difficulties by using more directive interaction strategies. Given that siblings of children with ASD have a higher risk of developing (characteristics of) ASD themselves, PCI research has also focused on those high-risk (HR) siblings. These studies have shown that HR siblings are less lively during PCI and that the ASD-specific (directive) parental interaction style seems to be (at least partly) generalized to the younger siblings. Given the positive association of PCI characteristics with later development, it is important to investigate developmental pathways of PCI characteristics and its possible impact on the development of HR siblings.

Objectives: The current study observed PCI in HR and low-risk (LR) siblings at five time points throughout the first three years of life. Maternal, infant and dyadic PCI characteristics were compared between groups and the link with later cognitive and social-communicative functioning was explored.

Methods: Unstructured play interactions of 76 mother-infant dyads (38 HR, 38 LR) were observed at 5, 10, 14, 24 and 36 months and coded with the Coding Interactive Behavior scheme (Feldman, 1998). Mullen Scales of Early Learning (MSEL) and ADOS-2 were administered at 10 (only MSEL), 14, 24 and 36 months.

Results: HR dyads were rated lower for dyadic reciprocity at 10 months, maternal limit setting and dyadic reciprocity at 24 months and infant involvement at 36 months.

Within the whole sample, the predictive value of PCI characteristics at 5 and 14 months for later social-communicative, cognitive and PCI characteristics was rather limited.

At 10 months PCI characteristics were predictive of ADOS scores at 14 and 24 months, MSEL subscale scores at 14 and 36 months, and PCI characteristics at 24 and 36 months. Finally, at 24 months infant negative emotionality during PCI was predictive of higher ADOS scores and lower MSEL scores at 36 months; and infant involvement was predictive of higher MSEL language scores at 36 months.

On the other hand, higher ADOS scores at 14 months predicted less maternal limit setting and infant involvement at 24 months and less infant involvement at 36 months. ADOS scores at 24 months predicted all PCI characteristics at 36 months.

Conclusions: Throughout the first three years of life PCI of HR siblings is characterized by lower levels of dyadic reciprocity, and a lower level of infant involvement at the age of three. Predictive value of PCI characteristics for later functioning is strongest at the ages of 10 and 24 months. On the other hand social-communicative functioning also predicts PCI characteristics at later ages. These bidirectional associations are in line with the transactional model of development. At the conference, the relationship between PCI characteristics and diagnostic outcome at 36 months and implications of the findings will be discussed.

11:45 **178.004** Daily Sources of Autonomy-Support and Control in Mothers of Children with ASD: The Role of Child Behavior and Mothers' Psychological Needs

L. M. Dieleman[1]*, S. S. De Pauw*[2]*, M. Vansteenkiste*[1]*, P. Prinzie*[3] *and B. Soenens*[1]*, (1)Department of Developmental, Personality, and Social Psychology, Ghent University, Ghent, Belgium, (2)Department of Special Needs Education, Ghent University, Ghent, Belgium, (3)Erasmus University Rotterdam, Rotterdam, Netherlands*

Background: Many parents would probably agree that, when it comes down to rearing children, one day is not the other. On some days, parents can be patient and sensitive towards their children without any effort, whereas on other days parents can experience difficulties to be attuned to their children's perspective and even inclined to interact with their children in a more pressuring fashion (Dix, 1991). Dairy studies in community samples have confirmed that controlling and autonomy supportive parenting behaviors vary considerably on a daily basis (e.g., Mabbe et al., in press). In parents of children with autism spectrum disorders (ASD), however, the short-term variability in parenting remains unexamined. Given that the specific symptoms and behaviors of children with ASD confront parents almost on a daily basis with unique challenges (e.g., Pottie, Cohen, & Ingram, 2009), it is important to advance the understanding of the daily dynamics in raising a child with ASD.

Objectives: To gain more insight in the sources of daily parenting among parents of children with ASD, this study aims to investigate whether daily variation in both child behavior and in mothers' own psychological needs (Deci & Ryan, 2000) relates to daily variation in controlling and autonomy-supportive parenting. In addition, this study aims to offer more insight into the mechanisms underlying these daily relations by examining the mediating role of daily parental vitality and stress.

Methods: Data will be presented from a 7-day diary study examining the daily associations between child behavior (i.e., externalizing and internalizing problems, prosocial behavior), mothers' psychological needs (i.e., autonomy, competence, and relatedness), parenting behavior (i.e., autonomy-support and controllingness), stress and vitality. In total 42 mothers (M_{age} = 41.60) of children with ASD (M_{age} = 10.94, range 7-15) participated.

Results: Analyses revealed that both daily child behavior and mothers' psychological needs relate to day-to-day variation in parenting behavior. Moreover, the majority of these relations could be accounted for by daily stress and vitality in the mother-child interaction. More specifically, the results revealed a maladaptive and an adaptive pathway: stress accounted for the associations of externalizing child problems and maternal need frustration with controlling parenting, whereas vitality accounted for the association between need satisfaction and autonomy support.

Conclusions: This study highlights (1) that parenting is a dynamic phenomenon among mothers of children with ASS, (2) the importance of both daily child behavior and mothers' own psychological functioning in parenting a child with ASD, and (3) the key role of daily stress and vitality in effects of daily antecedents on daily maternal parenting.

Panel Session
Sensory, Motor, and Repetitive Behaviors and Interests
179 - Brain-Behavior Mechanisms of the Sensory and Motor Features of Autism
10:30 AM - 12:30 PM - Willem Burger Hal

Panel Chair: Robin Shafer, *Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN*

Sensory and motor features are highly prevalent in autism spectrum disorder (ASD) and contribute to individual differences across the spectrum. They are often associated with “core” social-communication deficits and repetitive behaviors in ASD. However, these sensory and motor features remain understudied. Consequently, we lack rigorous methods for measuring them, and have limited understanding of their underlying brain-behavioral mechanisms and the contribution of sensory and motor processing differences to core aspects of ASD. Symposium speakers from several labs will present studies using various neural and behavioral measurement approaches to better understand sensory and motor symptoms in ASD. Ms. Zoltowski (Vanderbilt University) will present fMRI data demonstrating differences in neural processing of tactile stimuli in ASD. Ms. Shafer (Vanderbilt University) will present EEG and motor performance data demonstrating the role of sensorimotor integration in neural and behavioral adaptability and its relation to core characteristics of ASD. Dr. Ewen (Johns Hopkins University) will present data illustrating how individuals with ASD acquire the skills involved in visuomotor imitation. Dr. Mosconi (University of Kansas) will discuss the functional neural circuitry involved in translating sensory feedback into precise motor output in ASD. Together, these papers represent novel approaches for exploring this under-represented area of autism research.

10:30 **179.001** Differences in Temporal Profile of Brain Responses By Pleasantness of Somatosensory Stimulation in Individuals with ASD

A. Zoltowski[1], *M. D. Failla*[2], *E. J. Moana-Filho*[3], *G. Essick*[4], *G. Baranek*[5], *B. P. Rogers*[6,7] *and C. J. Cascio*[8], *(1)Vanderbilt University, Nashville, TN, (2)Psychiatry, Vanderbilt University, Nashville, TN, (3)Division of TMD and Orofacial Pain, School of Dentistry, University of Minnesota, Minneapolis, MN, (4)Department of Prosthodontics, School of Dentistry, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (6)Radiology and Radiological Sciences, Vanderbilt University, Nashville, TN, (7)Institute of Imaging Science, Vanderbilt University, Nashville, TN, (8)Vanderbilt University School of Medicine, Nashville, TN*

Background: Individuals with autism spectrum disorders (ASD) show varied behavioral responses to somatosensory stimuli, including hyper-reactivity to light touch and hypo-reactivity to pain. Investigation of the neural processing underlying these differences can be informed by previous fMRI studies of sustained painful stimuli. These studies have isolated three distinct phases of pain processing, including a late phase encompassing stimulus offset and reflecting cognitive-affective evaluation of pain (Moulton et al., 2012). Individuals with ASD show diminished response in the two later phases of this triphasic pattern (Failla et al., 2017), suggesting differences in pain evaluation but not sensation or perception. It is not known whether this is unique to painful stimulation or if this pattern extends to non-painful stimuli, either pleasant or aversive.

Objectives: Our objective was to investigate the temporal profile of brain responses to non-painful somatosensory stimulation in individuals with ASD.

Methods: 28 Adults (ASD=14, typically developing (TD)=14) underwent functional magnetic resonance imaging (fMRI) in a block design using 3 textures with previously normed pleasantness ratings in the general population (Essick et al., 2010): soft brush (pleasant), burlap (neutral), and plastic mesh (unpleasant). On each trial, a texture was stroked along the right forearm with moderate speed and pressure for 30 seconds. Changes in blood oxygenation level-dependent (BOLD) signal were analyzed during early, intermediate, and late phases, consistent with prior studies. Results were cluster-corrected, thresholding at $Z>2.3$ and $p< .05$.

Results: Between groups, we found significant differences (TD>ASD) in BOLD signal change for pleasant (brush) and neutral (burlap) textures. For the brush, the TD group had greater response in left postcentral gyrus and right superior parietal lobule during the early and intermediate phases (all peak Zs> 4.0, all $p_{corr} < .0001$). For the burlap, group differences were only significant during the early phase and occurred in the paracingulate gyrus ($Z_{peak}=4.16$, $p_{corr}<.005$) and right angular gyrus ($Z_{peak}=4.01$, $p_{corr}<.05$). There were no group differences for the plastic mesh texture.

Within groups, the TD group showed significant early and intermediate phase responses to all stimuli. The ASD group had a more limited pattern of response, with increased BOLD signal during the late phase for the burlap texture (Left Central Operculum/Insular Cortex, $Z_{peak}=3.62$, $p_{corr}<.005$) and during the early phase for the mesh texture (Right Parietal Operculum, $Z_{peak}=3.64$, $p_{corr}<.0001$ and Left Insula, $Z_{peak}=3.87$, $p_{corr}<.0001$).

Conclusions: Group differences for the more pleasant textures seemed driven by limited responding in the ASD group, who showed more reliable responses to more aversive stimuli. As cognitive-affective evaluation may be less critical for non-painful stimuli, the TD group did not show late phase responses; however, the late phase response to the neutral burlap in the ASD group may reflect difficulty evaluating ambiguous, neutral sensory stimuli. The finding of an intact early but not intermediate and late phase response by the ASD group to the mildly aversive mesh texture extends the finding by Failla et al. (2017) in pain processing, suggesting a continuum of aversive sensation for which cognitive-affective evaluative processes may be affected in ASD.

10:55 **179.002** Neural and Behavioral Mechanisms of Behavior Change and Adaptability: Examining the Role of Sensorimotor Integration in Autism

R. L. Shafer[1], *E. Solomon*[2], *K. M. Newell*[3], *M. Lewis*[4] *and J. W. Bodfish*[1,5,6], *(1)Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN, (2)Wesleyan University, Middletown, CT, (3)College of Education, University of Georgia, Athens, GA, (4)University of Florida, Gainesville, FL, (5)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (6)Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN*

Background: Unusual sensory symptoms and motor deficits are highly prevalent in autism spectrum disorder (ASD). They can emerge early in the development of ASD, before the core social deficits and repetitive behaviors emerge, and their prevalence suggests that deficits in sensorimotor integration may contribute to characteristic features of ASD. Sensorimotor integration is the process through which the brain uses continuous sensory information to produce flexible patterns of behavior that support adaptation to one’s surroundings. Thus, impairments in sensorimotor integration may contribute to the development of inflexible patterns of social and nonsocial behavior that characterize ASD. We currently lack techniques to precisely measure sensorimotor integration in ASD and so lack an understanding of the role it may play in ASD.

Objectives: Our study aimed to (1) develop a method to simultaneously assess neural and behavioral function during a sensorimotor task, (2) develop measures of the adaptability of neural and behavioral output during the sensorimotor task, and (3) examine differences in neural and behavioral adaptability in persons with ASD.

Methods: We designed a stimulus-tracking task with simultaneous recording of high density EEG. Participants used a computer mouse to control an on-screen cursor. They were instructed to keep the cursor inside of a target that moved across the screen in a series of unpredictable patterns. The task consisted of two sensory conditions: (1) Visual Feedback: target and cursor were visible on the screen for the duration of the trial, (2) No Visual Feedback: target and cursor were visible at the beginning of the trial, but disappeared mid-trial, and participants were instructed to continue moving the mouse as if the target and cursor were still visible. Participants included young, right-handed adults with ASD (N=20) and an age- and gender-matched typically developing group (N=18). We analyzed group and visual feedback effects on motor performance (root mean squared error of cursor position), motor complexity (sample entropy), and neural complexity (multi-scale sample entropy).

Results: Participants show significantly greater error in task performance when visual feedback is not available (t=10.39, p<0.001). Consistent with this finding, motor complexity is significantly reduced in the absence of visual feedback (t=23.59, p<0.001), indicating more stereotyped patterns of movement when feedback is not available compared to when it is. Participants also demonstrate lower neural complexity in task-relevant scalp regions when feedback is withheld (Frontal: t=3.29, p=0.006; Occipital: t=3.07, p=0.009), paralleling the patterns of motor complexity.

Conclusions: Our results indicate that reliable sensorimotor integration and the availability of sensory feedback provide the brain with rich information with which to generate complex, adaptive motor output. In the absence of sensory feedback, the neural signal contains less information and correspondingly, the motor signal is more stereotyped and inflexible, thus this task provides a standardized, objective measure of inflexible, stereotyped behavior. Sensorimotor integration is likely disrupted in individuals with ASD resulting in less complex neural signals and consequently less complex, less adaptive behavior. Our ongoing work involves adapting our sensorimotor task into a “game-like” virtual reality environment, which allows assessment at earlier periods of development.

11:20 **179.003** Capacity Limits and Learning: Two Views of Altered Visuo-Motor Imitation in ASD

J. B. Ewen[1,2]*, S. H. Mostofsky*[3]*, A. S. Pillai*[1,2] *and D. McAuliffe*[1]*, (1)Kennedy Krieger Institute, Baltimore, MD, (2)School of Medicine, Johns Hopkins University, Baltimore, MD, (3)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD*

Background: Impairments in visuo-motor imitation have been recorded in ASD since the 1970's, and are believed by some to have a fundamental, causal role in the development of the disorder. What is less well understood is how these imitation deficits come about. Based on clinical experience, we have developed two hypotheses regarding the basis for these imitation deficits. The first centers around capacity limitations. Specifically, we have noted that children with ASD have a challenge imitating gestures when they are required to do two components simultaneously. On the other hand, we also suggest a framework for impaired gesture imitation in which children with ASD may have trouble building up representations of the novel gestures through impaired learning mechanisms.

Objectives: We tested these two hypotheses regarding the basis for altered imitation in ASD independently.

Methods: Study 1A: High-functioning children with ASD aged 8-12 years and age- and IQ-matched controls (n = 25+25) were asked to imitate 9 novel, meaningless gestures with their right hand in which movement elements (e.g., supinate the forearm, flex fingers 1 and 2) were all serial, and 7 gestures in which these elements were overlapping (simultaneous). Performance was recorded as correct or incorrect. Study 1B: 15 pairs of gestures were constructed in which there was a serial version and an simultaneous version. 7 children with ASD and 7 controls participated. Study 2A: 4 children with high-functioning ASD and 5 controls participated in a novel gesture learning task, in which they watched videos of a model performing a meaningless gestures. At a Go cue, they copied that gesture and were scored as performing it correctly or incorrectly. They repeated this cycle 5 more times with the same gesture. 12 gestures were tested. Study 2B: Similar to 2A, but with four repetitions of each gesture. 16 children with ASD and 17 controls participated.

Results: Study 1A: Main effects were seen for diagnosis (ASD had more errors than TD) and for gesture type (simultaneous gestures evoked more errors than serial). The central finding was the interaction effect: children with ASD had greater performance cost for simultaneous (over serial) gestures than controls. Partial eta squared: 0.21, p=0.001. This effect size stayed constant even when controlling for the total number of elements in each gesture. Study 1B: When the serial and simultaneous gestures were paired (i.e., the only difference was the relative timing of the two elements), there were no group differences in serial gesture error rates. The group x gesture-type interaction effect size was 0.42 (partial eta squared), p = 0.017. Study 2A: Children with ASD took an average of 4.0+/-2.3 trials to perform a gesture correctly; TD, 2.7+/-2.1 (p=0.013). Study 2B: Children with ASD took an average of 3.3+/-2.3 trials to perform a gesture correctly; TD, 2.3+/-1.7 (p=0.01).

Conclusions: There is independent evidence for both accounts of impaired imitation in ASD--a more restrictive capacity limitation, and impaired learning of the motor representation. Work using EEG to establish neural correlates is ongoing.

11:45 **179.004** The Functional Neuroanatomy of Visuomotor Impairments in ASD

M. W. Mosconi[1]*, K. E. Unruh*[1]*, R. J. Lepping*[2]*, Y. Wang*[3]*, L. M. Schmitt*[4]*, Z. Wang*[5]*, S. Lui*[3]*, D. E. Vaillancourt*[6] *and J. A. Sweeney*[7]*, (1)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (2)Hoglund Brain Imaging Center, University of Kansas, Kansas City, KS, (3)Huaxi MR Research Center (HMRRC), Department of Radiology, West China Hospital of Sichuan University, Chengdu, China, (4)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)Department of Occupational Therapy, University of Florida, Gainesville, FL, (6)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (7)Division of Developmental Behavioral and Pediatrics, Cincinnati Children’s Hospital Medical Center, Cincinnati, OH*

Background: Sensorimotor impairments are common in ASD and associated with worse functional outcomes. We previously documented increased force variability during continuous visuomotor behavior in ASD. Patients’ visuomotor deficits were more severe when the force required or the precision of visual feedback were increased implicating both motor and sensory feedback processes. Characterizing the neural processes associated with visuomotor deficits in ASD will help determine mechanisms of sensorimotor issues and related daily living skills.

Objectives: We will describe new results on neural processes associated with sensory feedback and motor control processes during visuomotor behavior in ASD.

Methods: Individuals with ASD aged 11-30 years and age-matched controls completed three functional MRI (fMRI) studies. For studies 1 and 2, participants completed visuomotor tasks in which they pressed with their thumb and index finger on a force transducer while viewing a white FORCE bar on a screen that moved upwards with increased force toward a fixed green TARGET bar. Participants were instructed to maintain the FORCE bar at the level of the TARGET bar for 26 seconds. For study 1, 20 participants with ASD and 15 controls pressed at 20 and 60% of their maximum force. For study 2, a separate 25 individuals with ASD and 22 controls pressed at 15% of their maximum force across three different visual feedback gain levels. At higher visual gains, the white FORCE bar moved a greater distance per change in Newtons of force relative to lower gains. For study 3, the same participants who performed study 1 completed a resting functional scan.

Results: During study 1, individuals with ASD showed reduced activation of contralateral motor cortex (M1), superior parietal lobule (SPL), and ipsilateral cerebellar lobules V-VI compared to controls. These hypoactivations were more severe at higher force levels. Individuals with ASD also showed greater activation than controls in middle frontal gyrus, supplementary motor area (SMA) and striatum at both force levels. During study 2, reduced M1, SPL and ipsilateral cerebellar activation was seen in ASD relative to controls at low visual gain. At high gain, individuals with ASD showed greater activation than controls in SPL. During rest, reduced SMA and cerebellar ALFF and reduced striatal-cortical and cerebellar-cortical connectivity each were associated with visuomotor deficits in ASD (r's>.6; p's<.05 corrected).

Conclusions: These studies indicate that elevated motor variability in ASD is associated with intrinsic alterations of frontal, parietal, striatal and cerebellar function and connectivity. We found that parietal-cerebellar-M1 circuits involved in reactively adjusting motor output in response to visual feedback are underactive and less able to support precise motor behavior in ASD. Elevated frontostriatal activation in ASD suggests that brain systems typically involved in higher-level cognitive control may compensate for visuomotor network underactivity. Greater parietal activation in ASD at high visual gain suggests that deficient motor control during conditions of increased sensory load reflects hyper-reactivity of visual processing brain circuits. Together, these results indicate that atypical neural processes involved in translating sensory feedback into precision behavioral output represents a significant component of the neurodevelopmental processes that cause ASD.

Panel Session
Diagnostic, Behavioral & Intellectual Assessment

180 - Leveraging the Strengths of People with ASD: A Strengths-Based Approach to Intervention

10:30 AM - 12:30 PM - Jurriaanse Zaal

Panel Chair: Sven Bolte, *Center for Neurodevelopmental Disorders (KIND), Center for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden*

While the abilities and strengths of people with autism spectrum disorder (ASD) are increasingly recognized, developing strengths-based interventions is hampered by a lack of consensus in regard to their commonly occurring skills and abilities, failure to articulate strengths-based frameworks, and the absence of multiple perspectives in identifying the mechanisms of strengths-based approaches, including those of people with ASD themselves. In this symposium we present findings from four projects adopting a strengths-based approach: The development of ICF core sets for ASD; a scoping review of the literature relating to strengths-based programs underpinning a provisional strengths-based framework; a realist evaluation of computer coding groups for adolescents with ASD employing multiple ethnographic methods defining the context, mechanisms and outcomes of the program; and, the self-reported viewpoints of adolescents diagnosed with ASD, their parents and coding mentors in relation to their participation ASD specific computer coding clubs.

10:30 **180.001** Abilities and Strengths of Individuals on the Autism Spectrum from a Global Perspective: Findings from the ICF Core Sets for Autism Development

__S. Mahdi__[1] and S. Bolte[2], (1)Karolinska Institutet Center of Neurodevelopmental Disorders (KIND), Karolinska Institute Center of Neurodevelopmental Disorders, Stockholm, Sweden, (2)Center for Neurodevelopmental Disorders (KIND), Center for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden

Background: Autism Spectrum Disorder (ASD) is associated with a wide range of social, occupational and educational challenges, but also strengths. To date, no standardized, internationally accepted tools exist to assess ASD-related strengths. The WHO's International Classification of Functioning, Disability and Health (ICF) can serve this need The ICF is based on a bio-psycho-social model of functioning, comprising of over 1600 categories related to various components of health: body functions, body structures, activities, participation and environmental factors. Not all are, however, applicable to a certain condition, which is why the process has been initiated to develop ICF Core Sets for Autism Spectrum Disorder (ASD); lists of generally-agreed-upon ICF categories pertinent to individuals with a certain health condition.

Objectives: We present the results of ASD-related strengths that were identified in our efforts to develop ICF Core Sets for ASD. The efforts included more specifically three cross-cultural and trans-disciplinary studies: an expert survey, a qualitative study and a clinical study.

Methods: The expert survey included 225 international experts representing 11 different disciplines and 43 countries across all six WHO-regions. The survey contained 7 questions related to functioning, of which one inquired about ASD-related strengths. The qualitative study involved focus group discussions and semi-structured interviews with individuals with ASD, family members and professional caregivers from 19 stakeholder groups in 5 countries from 5 WHO-regions. Qualitative content analysis was performed to extract meaningful concepts from survey responses and transcripts. These were then linked to ICF codes (if applicable) following specific linking rules. The ICF linking was not necessary in the clinical study. Instead, an extended version of ICF checklist (containing ICF categories) was used by clinicians to gather data from 122 individuals with ASD recruited at 11 clinical sites in 10 countries in 4 different WHO-regions. Frequency analysis was conducted in all studies to identify most common reported ASD-related strengths

Results: A large majority of experts (n = 207, 92%) indicated at least one ASD-related strength. The most common ones were b126 temperament and personality functions (n = 68, 30%; e.g. strong sense of morality), b140 attention functions (n = 67, 30%; e.g. attention to detail, intense focus) and specific expertise in a field (n = 52; 23%; e.g. video games, geographical facts). All stakeholder groups in the qualitative study identified at least one ASD-related strength, which included b126 temperament and personality functions (n = 8, 42%; e.g. honesty), b140 attention functions (n = 6, 32%; e.g. attention to detail) and b144 memory functions (n = 5, 26% e.g. memory for specific events). The clinical study yielded two ICF categories, namely b140 attention functions (n = 27, 21%) and b144 memory functions (n = 20, 16%).

Conclusions: Irrespective of study methodology and perspective, certain ASD-related strengths (e.g. memory, attention) were found to be recurring and important to functioning. The information on strengths can be meaningful for a variety of purposes. It can serve as basis for developing resource-oriented interventions in clinical settings to matching job assignments with individual strengths in employment services

10:55 **180.002** Strengths-Based Computer Coding Groups for Adolescents with ASD: A Realist Evaluation

__M. Jones__[1] and S. J. Girdler[2], (1)School of Occupational Therapy and Social Work, Curtin University, Bentley, Australia, (2)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia

Background: While research suggests that there has been much progress in improving outcomes for children and adolescents with Autism Spectrum Disorder (ASD) adult outcomes continue to be less than optimal. Specifically, the employment rate of individuals with ASD internationally remain poor. Strengths-based programs leverage individual strengths, potentially building skills that could assist in preparing adolescents with ASD for work and adult life, ultimately improving outcomes. Strengths-based programs focus on pathways for the future rather than trying to 'fix' impairments. However, little is known as to what constitutes a 'strengths-based program' and few studies document the active ingredients or the essential components of programs that result in a positive change in participants.

Objectives: To synthesise literature describing strengths-based programs for individuals with ASD and define their active ingredients.

Methods: A scoping review of strengths-based programs for individuals with ASD was undertaken. Database searches of AMED, CINAHL, MEDLINE, PsychINFO, EMBASE, Cochrane Library, Scopus and ERIC were undertaken for studies published between 1990 and 2017. Studies recruiting participants of any age with a diagnosis of ASD and claiming to describe a 'strengths-based program' were included. Descriptive data such as author, publication date, country, sample characteristics, aim, methodology, intervention type, outcome measures and results were extracted. The methodological quality of the studies was assessed via the quality assessment tool developed by Kmet, Lee and Cook. Thematic analysis identified the active ingredients of the strengths-based programs described in the studies which were linked to the International Classification of Functioning, Disability and Health (ICF) Core Sets for ASD. Consultation with stakeholders occurred in interpreting the results.

Results: Searches of relevant databases identified a total of 27 articles. Twenty articles evaluated strengths-based programs for individuals with ASD, including 9 qualitative and 11 quantitative studies, which ranged in methodological quality from limited (k=3) to very strong (k=11). The remaining articles (k=7) consisted of published feature or discussion articles and did not include or report any research methods. All articles were published between 2003 and 2017, with the majority of undertaken in the United States of America (k=20). Thematic analysis revealed ten major themes representing the active ingredients of strength-based programs for individuals with ASD; interests, family involvement, skill development, visual instruction, reframing weaknesses, autonomy, peer mentoring, routine, adult mentors and talents. Linking to the ICF Core sets for ASD highlighted the importance of environmental factors including *Chapter 1 Products and technology* and *Chapter 3 Support and relationships* in underpinning strengths-based programs.

Conclusions: While there is a paucity of research evaluating the efficacy of strengths-based programs for individuals with ASD and what constitutes a 'strengths-based program' is poorly defined in the literature, this review articulates for the first time a framework with the potential to underpin future programs. Future research is needed to evaluate the effectiveness of programs underpinned by these active ingredients in improving outcomes for people with ASD.

11:20 **180.003** Strengths-Based Programs for Individuals with Autism Spectrum Disorder: A Scoping Review Defining the Active Ingredients

M. Jones[1] *and S. J. Girdler*[2]*, (1)School of Occupational Therapy and Social Work, Curtin University, Bentley, Australia, (2)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia*

Background: While it is widely recognized that many individuals with Autism Spectrum Disorder (ASD) have abilities and strengths well suited to employment in the Information Communication Technology (ICT) industry, they continue to be under represented in this industry and their overall employment rate remains less than optimal. It has been proposed that employment outcomes in adulthood for people with ASD could be improved through strengths-based programs that leverage strengths, capitalize on existing skills and prepare adolescence with ASD for work. The Autism Academy of Software Quality Assurance (AASQA) and Autism West in Western Australia both deliver strength-based programs targeted at adolescents with ASD with interests in Science, Technology, Engineering, Arts and Mathematics (STEAM). A significant focus of these programs is computer coding clubs which draw from the CoderDojo approach which aims to provide a fun, free and social open learning environment where young people can meet others with similar interests to themselves, develop 21st century skills and build creative projects of their own choice using digital technology.

Objectives: To define the context, mechanisms and outcomes of strengths-based computer coding groups for adolescents with ASD.

Methods: A realist evaluation was employed triangulating ethnographic data collection methods (participant observations and focus groups) and investigators (two observers). Observations were undertaken during eight sessions of computer coding groups for 17 adolescents with ASD and five program mentors or facilitators. Focus groups were conducted with seven adolescents with ASD who had attended the computer coding groups, nine of their parents, and nine mentors or facilitators. Field notes and focus group discussions were transcribed verbatim and coded using the context, mechanism and outcome framework. Context refers to anything that was present prior to the intervention program, inclusive of personal factors. Mechanisms include program components that lead to change. Outcomes refer to changes that occur as a result of the strength-based program.

Results: Themes within the context category were personal factors of students with ASD, personal factors of facilitators and expectations of parents. Themes within the mechanism category were adaptable environment, facilitator-student interaction, student-student interaction, match between facilitators and mentors technical computer skills and student interests, shared interests, autonomy and goal setting. Themes in the outcome category included social engagement, skill development, goal achievement, confidence and motivation.

Conclusions: This study highlights the mechanisms of a strengths-based computer coding group, the context in which mechanisms occur and the outcomes for adolescents with ASD. The main findings emphasized the importance of matching the technical skills of facilitators with student interests, providing an adaptable environment and achieving social and technical skill outcomes. These findings, combined with those of previous strengths-based research in ASD, could potentially inform the development of a strengths-based framework to underpin future Science, Technology, Engineering, the Arts and Mathematics (STEAM) programs for young people with ASD. Future research should evaluate the effectiveness of STEAM programs underpinned by this framework in improving outcomes for people with ASD.

11:45 **180.004** Social Coding: The Viewpoints of Adolescents with ASD, Their Parents and Mentors on Participation in Social Coding Clubs

K. Catto[1]*, M. Falkmer*[2]*, S. J. Girdler*[3] *and M. Jones*[4]*, (1)School of Occupational Therapy and Social Work, Curtin University, Perth, Australia, (2)School of Occupational Therapy and Social Work, Curtin University, Perth, Western Australia, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia, (4)School of Occupational Therapy and Social Work, Curtin University, Bentley, Australia*

Background: While it is clear that people living with ASD experience challenges in social communication and interaction, there is increasing evidence that social functioning can be improved by providing opportunities to socialise in supported and structured environments. Parallel to this research there is emerging appreciation that many individuals with ASD possess abilities and strengths, including attention to detail and an affinity for rule based activities such as computer coding. It is likely that programs combining a group approach with an activity focus, such as computer coding, will be particularly engaging for adolescents with ASD. However, little is known of the experience of young people with ASD attending such programs, or the viewpoints of their parents or mentors on these programs.
Objectives: This study explored the viewpoints of adolescents diagnosed with ASD, their parents and coding mentors in relation to their participation in community computer coding clubs specifically targeted at adolescents with ASD.

Methods: Q methodology, which enables viewpoints to be obtained without an interview, was employed facilitating an in-depth understanding of attitudes and beliefs of participants regarding their experience of computer coding group. The Q methodology in this study followed the five stage procedure of: 1) Developing the concourse to gain insight into broad attitudes and beliefs of people involved in ASD-specific coding groups; 2) Identifying Q Sort statements guided by the concourse and the 'Five C's model' of Positive Youth Development; 3) Administering the Q Sort electronically or via a physical Q Sort grid and statement cards; 4) Factor Analysis using PQ method software; and, 5) Interpretation of factors. A total of 54 participants completed the Q Sort: 16 adolescents with ASD, 10 parents and 28 mentors.

Results: Two viewpoints were identified by adolescent participants and a total of three viewpoints were identified by parent and mentor participants. All adolescent participants loaded significantly onto either *Viewpoint 1) "Social coding is cool"*, or *Viewpoint 2) "Community coding is cool"*. In contrast, 11 parent/mentor participants loaded significantly onto either *Viewpoint 1) "Social coding is a pathway to the future", Viewpoint 2) "Social coding is challenging"*, or *Viewpoint 3) "Mentored coding is cool"*.

Conclusions: Findings highlighted that adolescents with ASD highly valued the social aspects of the computer coding clubs, while parents saw the coding clubs as a pathway to future job opportunities and as an opportunity for skill development. These divergent viewpoints underline the importance of consulting both adolescents with ASD and their parents in developing engaging and effective group interventions. Mentors also played a central role in facilitating the development of coding skills and social interaction. This study suggests that computer coding clubs are an approach which provides an opportunity to both practice and develop social skills and to learn technical coding skills, both of which are beneficial in the pathway to adult roles including employment.

Panel Session
Service Delivery/Systems of Care
181 - Developing ASD Interventions for End-Users: Examining the Process and Impacts of Training Providers in Multiple Community Service Systems
10:30 AM - 12:30 PM - Arcadis Zaal

Panel Chair: Lauren Brookman-Frazee, *Psychiatry, University of California, San Diego, San Diego, CA*

Discussant: David Mandell, *Center for Mental Health, University of Pennsylvania, Philadelphia, PA*

The purpose of this panel is to describe community-partnered research aimed to develop and test clinical and service interventions for delivery in community services caring for children with ASD: early intervention, education, mental health, and primary care. These studies share a common focus on developing feasible and effective provider training models to enhance child outcomes in routine care. The first presentation describes the impact of a train-the-trainer implementation model for a naturalistic developmental behavioral intervention for infants and toddlers delivered in early intervention services on agency leader training outcomes. The second presentation reports results from a large-scale effectiveness trial including teacher and students outcomes when teachers were trained to deliver a behavioral classroom intervention. The third presentation reports results from a large-scale effectiveness trial of a behavioral intervention in publicly-funded mental health services including the impacts of training therapists on therapist practice and child symptoms. The final presentation reports initial qualitative themes from a new program of research aimed to enhance primary care provider training in integrated care for children with ASD. Dr. David Mandell, will highlight themes across studies and propose recommendations for developing interventions and training models for the targeted community services caring for children with ASD.

10:30 **181.001** Building Community Capacity for Evidence-Based, Parent-Mediated Early Intervention: Effectiveness of a Train-the-Trainer Approach

A. C. Stahmer[1], *S. R. Rieth*[2,3], *K. S. Dickson*[3], *K. L. Searcy*[4], *J. Feder*[5] *and L. Brookman-Frazee*[6], *(1)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (2)San Diego State University, San Diego, CA, (3)Child and Adolescent Services Research Center, San Diego, CA, (4)Speech & Language, San Diego State University, San Diego, CA, (5)Child and Family Psychiatrist Tertiary Outpatient and Neurobehavioral Medicine Private Practice, Solana Beach, CA, (6)Psychiatry, University of California, San Diego, San Diego, CA*

Background: Parent-mediated naturalistic developmental behavioral interventions (NDBI) have demonstrated positive child and family outcomes for young children with ASD (Zwaigenbaum et al., 2015; Burrell & Borrego, 2012). Despite demonstrated benefits, however, there has been little dissemination of parent-mediated NDBI into community settings, where the majority of children receive services (Stahmer et al., 2016). Community providers with expertise in both the NDBI strategy use and partnering with parents are needed to effectively deliver NDBIs. However, based on the range of mechanisms and avenues through which children with ASD may receive services, community providers have variable educational backgrounds and ASD specific experience. As communities struggle to serve the growing number of young children with ASD with appropriate intervention, more information is needed on effective provider training that adequately equips interventionists to work effectively with families and meet the specialized needs of children with ASD.
Objectives: The objective of this presentation is to demonstrate training outcomes from a train-the-trainer study of an evidence-based, parent-mediated NDBI for community early interventionists (Project ImPACT for Toddlers or PI for T; Ingersoll & Dvortscak, 2010).

Methods: A multiple probe design was used to examine effectiveness of the training model. Fourteen leaders from 12 publicly-funded community agencies participated. Agencies included school-based early intervention (N=2), infant and early childhood services (N=6), speech language (N=1), ASD specific agencies (N=1) and a Children's Hospital ASD clinic (N=1), and family health programs (N=1). Agency leaders received 12 weeks of training in PI for T from the research team. Leaders were trained in groups of 4-5, per the multiple probe design. After agency leader training was complete, each leader returned to their individual agency to deliver training to 2-3 interventionists (45 providers total). Intervention fidelity in PI for T was measured across the training period (before, during and after) at multiple time points. A total of nineteen fidelity criteria were rated on a 1-5 scale, where 1 = does not implement and 5 = implements competently and consistently.

Results: Agency leaders (n=14, 100%) were successfully delivered training at their agencies, utilizing both online (n=3) and in-person approaches (n=11). Intervention fidelity data are variable but demonstrate growth for strategies that providers were not implementing at baseline. On average, providers were using 21% of strategies correctly at baseline strategies (M=3.5 or above), including limiting distractions in the environment (baseline M = 4.1) and adjusting animation (baseline M=3.6). After training, on average, providers were using 74% of strategies correctly; waiting for a child response (baseline M=3.2, post-training M=3.8) and making comments/avoiding questions (baseline M=3.3, post-training M=4) demonstrated the most change. Specific support for sustainment beyond the training period (e.g., assistance securing public funding) facilitated agencies' continued use of the approach. Differences in post-training fidelity based on provider and agency characteristics will also be explored.

Conclusions: A train the trainer model is an effective method to build community capacity for evidence-based early intervention across a range of service settings. It may be possible to deliver training more efficiently by tailoring training to gaps in provider knowledge.

10:55 **181.002** Examining Effectiveness of Classroom Pivotal Response Teaching in Public Schools

__J. Suhrheinrich__[1], S. R. Rieth[1,2], S. Roesch[1] and A. C. Stahmer[3], (1)San Diego State University, San Diego, CA, (2)Child and Adolescent Services Research Center, San Diego, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA

Background: Autism interventions that are shown to be efficacious in controlled research settings are often not well integrated into schools, demonstrating the need for translation or adaptation for classroom use. These practices can be systematically adapted to ensure a fit with student and classroom characteristics while maintaining the active ingredients of the intervention. Such adaptations should improve teachers' fidelity of implementation of the intervention (FI; the degree to which the intervention is being applied as specified in the treatment manual) and thus facilitate better outcomes for students (e.g., Durlak & DuPre, 2008; O'Donnell, 2008; Sanetti & Kratochwill, 2009; Stahmer & Gist, 2001). Classroom Pivotal Response Teaching (CPRT) is a behavioral intervention for children with ASD adapted from Pivotal Response Training through an iterative process in collaboration with researchers, teachers, and school administrators (Stahmer, Suhrheinrich, & Rieth, 2017).
Objectives: This presentation will provide teacher outcomes from a large-scale community effectiveness trail of CPRT in schools including teacher and preliminary student outcomes.

Methods: The study used a randomized waitlist-control design with 108 classrooms (including the lead teacher and paraprofessional educators) over three years. Teachers (n=109) and students (n=256) from 17 school districts participated. Training procedures included 12 hours of small group didactic instruction, including goal setting, supervised exercises and role-playing. Individual coaching followed at weekly, then monthly intervals upon completion of didactic training. During coaching, teachers worked with their own students during regular classroom activities. Teacher measures included the Professional Development Assessment (PDA), fidelity of CPRT use and satisfaction surveys. Child measures included the ADOS, cognitive assessment, Vineland Adaptive Behavior Scales (VABS) and Pervasive Developmental Disability Behavioral Index (PDDBI).

Results: On average, trained teachers reported using CPRT for 50 min/day, and 3 days per week, with 37% of teachers using CPRT at least 4 days/week. Multilevel models indicated significantly higher fidelity of CPRT (as coded by naïve observers) for teachers who completed training as compared to control teachers (B=0.27, p=.001). Seventy-three percent of teachers met fidelity criteria (trainer coded) for CPRT after an average of 7.6 coaching sessions. Preliminary student data indicate significantly greater change on PDDBI during the training compared to control year. Scores on some scales were moderated by student age, teacher experience and classroom quality.

Conclusions: Results indicate CPRT is feasible in classroom settings and classroom teachers can be trained. Preliminary student outcomes are promising. Findings suggest collaborative adaptation of evidence-based practices may facilitate fidelity of the intervention in community settings. Considerations for sustainment and improving community outcomes will be discussed.

11:20 **181.003** Training Community Mental Health Providers to Deliver an Intervention for Children with ASD: Impacts on Therapist Practice and Child Behaviors

__L. Brookman-Frazee__[1], C. Chlebowski[2] and S. Roesch[3], (1)Psychiatry, University of California, San Diego, San Diego, CA, (2)National Institute of Mental Health, Bethesda, MD, (3)San Diego State University, San Diego, CA

Background:Publicly-funded mental health (MH) services play an important role in caring for school-age children with ASD. AIM HI ("An Individualized Mental Health Intervention for ASD", Brookman-Frazee and Drahota, 2010) was developed based on a systematic needs assessment and in collaboration with community stakeholders in response to the need for a scalable intervention for delivery in MH programs. AIM HI is a package of well-established parent mediated and child-focused behavioral strategies designed to reduce challenging behaviors, the most common presenting problem for children with ASD in MH services. The current study examined the impact of training community therapists to deliver AIM HI. Data were drawn from a completed large-scale randomized community effectiveness trial of AIM HI conducted in publicly-funded outpatient and school-based MH programs.
Objectives: The purpose of this study was to examine the impact of training community MH therapists to delivery AIM HI to their clients on observed therapist practice and child behavior problems and to identify therapist perceptions and child factors associated with these outcomes.

Methods: A waitlist controlled design was used in which 29 MH programs were randomized to either immediate AIM HI training or Usual Care/Delayed AIM HI training conditions. Therapist and client dyads were recruited from with enrolled programs. A total of 202 client/therapist dyads were included. Therapists were 86% female and 33% Latino and children (*M* age = 9.1 years) were 82% male and 56% Latino. Session-level therapist fidelity was collected over the 6 month training period during which the therapist delivered AIM HI to their client while receiving performance feedback from an AIM HI trainer. Specifically, video recordings of 1,153 psychotherapy sessions were coded for adherence to active teaching strategies (e.g., modeling, behavioral rehearsal) directed to children and parents. Therapists reported on their confidence using active teaching strategies at baseline. The Eyberg Child Behavior Inventory (ECBI) was completed by parents at baseline, 6 months (post), and 12 and 18 month follow up.
Results: AIM HI adherence was significantly higher for therapists who received AIM HI training compared to Usual Care therapists (B=1.40, p<.001).

Therapist self-reported pre-training confidence was associated with adherence directed to children (B=.17, p=.05). Results from three-level (time nested within child within program site) mixed effects modeling controlling for ASD severity and program setting (school, clinic) revealed a significant group by time interaction for ECBI Intensity scores (B=-0.38, p.015). Follow-up tests showed a significantly greater decline across the four time-points in the AIM HI training group (B=-1.36, p<.001) relative to the Usual Care group (B=-0.98, p<.001). Therapist AIM HI adherence and child behaviors in session significantly moderated this effect.

Conclusions: These results provide empirical support for the effectiveness of AIM HI on a key targeted outcome when delivered by community mental health providers and highlight the importance of therapist fidelity on outcomes. Next steps in the research include a recently-initiated, large scale implementation trial examining training and implementation leadership strategies to improve therapist fidelity.

11:45 **181.004** Enhancing Provider Training in Integrated Mental Health Care for ASD: Perspectives from Primary Care Providers and Leaders

N. A. Stadnick[1] *and S. broder-Fingert*[2]*, (1)University of California San Diego, La Jolla, CA, (2)Pediatrics, Boston University, Boston, MA*

Background: Children with autism spectrum disorder (ASD) have high rates of co-occurring psychiatric symptoms or diagnoses (e.g., Joshi et al., 2010) that necessitate mental health care. However, there are often challenges in timely identification of mental health comorbidities and linkage to services, resulting in high rates of unmet mental health needs (Farmer et al., 2014). Pediatric primary care is well-positioned to screen for and link children with ASD to needed mental health services earlier (Asarnow et al., 2015). However, these integrated care procedures need to be tailored for children with ASD to facilitate access to and receipt of mental health care. Detailed information from pediatric primary care stakeholders related to mental health screening and referral practices and perceived training needs to improve this process are needed for successful tailoring and implementation of integrated care for children with ASD.

Objectives: In this qualitative study, the perspectives of primary care providers and organizational leaders regarding the current infrastructure and needs of primary care providers to enhance integrated mental health care for ASD were examined.

Methods: Data were drawn from the first phase of a larger implementation study that will adapt and implement an integrated care model for children with ASD and co-occurring mental health concerns. Focus groups and key informant interviews were conducted with 12 pediatric primary care leaders and providers from two large health care organizations in Southern California that provide primary care to children with ASD. Participants were asked about current mental health screening and linkage procedures and how they modify these procedures for their patients with ASD.

Results: Discovery-oriented qualitative analyses revealed preliminary themes about provider experiences in mental health screening and referral with children with ASD. Primary care providers confirmed that the majority of their school-age patients with ASD exhibit symptoms of co-occurring psychiatric conditions, notably disruptive behaviors and anxiety. However, there is a paucity of standard mental health screeners administered to school-age children, placing the burden on caregivers or providers to identify and express psychiatric concerns about the child. Primary care providers often spend significantly more time (compared to patients without ASD) supporting caregivers to follow through on a mental health referral. The reasons for this are multifactorial but due, in part, to provider perception that caregivers may not view mental health care as a top priority or distinct from other recommended or ongoing treatment services (e.g., applied behavior analysis, educational supports).

Conclusions: These initial findings confirm the need for tailored integrated mental health care procedures for children with ASD. Further, findings highlight potential targets for provider training including selecting and using efficient and effective mental health screening tools and strategies to engage and empower caregivers to facilitate access to mental health services. Qualitative data from an additional 40 primary care providers and leaders will be analyzed and integrated. Further implications for integrated care provider training and research will be discussed.

Poster Session
182 - Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG)
11:30 AM - 1:30 PM - Hall Grote Zaal

1 **182.001** Accurate Prediction of Individual Subject Identity and Task -- but Not ASD Diagnosis -- from Functional Connectomes

L. Byrge *and D. P. Kennedy, Psychological and Brain Sciences, Indiana University, Bloomington, IN*

Background: There is currently much interest in using functional connectivity (FC) MRI to identify neural biomarkers of ASD. However, for FC-based biomarkers to be useful, we need to know whether FC measurements are reliable in individuals with ASD and whether FC can robustly differentiate diagnostic groups (ASD vs. controls). Progress toward addressing these issues should also provide insights into the biological bases of ASD, including the neural heterogeneity or homogeneity of the condition.

Objectives: To evaluate FC reliability and predict diagnosis group in a sample of adults with ASD and controls using extensively and densely sampled fMRI data from each subject.

Methods: We acquired multiband resting-state and video-watching scans (813ms TR) from 29 adult controls and 22 matched individuals with ASD across multiple scan sessions, comprising over 2 hours of functional data per individual. Preprocessing, denoising, parcellation, and censoring are described in Byrge & Kennedy (in revision; see also Burgess et al., 2016). We computed correlations between each pair of FC matrices to assess similarity of FC. We used general linear mixed models to assess group differences in reliability and in similarity to NT scans while controlling for noise covariates. We used “connectome fingerprinting” (Finn et al., 2015) to predict identity, diagnosis, and scan type (rest/video) from maximal pairwise similarity. We also trained a classifier on the most informative FC edges to predict diagnosis and scan type while also controlling for noise covariates, extending the method of Shen et al. (2017). For visualization, we conducted multi-dimensional scaling.

Results: Within-individual consistency of functional connectomes did not differ across groups (rest/video, *p*=.14/.33, n.s.), indicating equivalent reliability across scans. Individual connectomes were highly distinct from other individuals, such that we could predict subject identity with 98% accuracy (see also Fig. 1, with subject scans generally clustering together). Using the same fingerprinting method, however, we could not predict subject diagnosis (56.8% accuracy, see also Fig. 2a), even though scans from the ASD group were reduced in similarity to NT scans (rest/video, *p*=0.026/.017). In contrast, this same method could be used to predict scan type (rest/video) with 97.6% accuracy (see also clear clusters in Fig. 2b), indicating that scan type elicited a stronger common FC pattern than diagnosis. Similar results were obtained using classifiers trained on only the most informative FC edges (60% accuracy for diagnosis; 96.8% accuracy for scan type). MDS results (Fig. 2a) depict scans from individuals with ASD spread farther apart from NT scans (i.e., more dissimilar) in all directions, without forming a common cluster, suggesting heterogeneous presentations of functional connectivity in ASD.

Conclusions: Our findings indicate that, at the spatial and temporal scale analyzed, functional connectomes in individuals with ASD present heterogeneously (consistent with our previous work; Byrge, Dubois, et al., 2015), rather than sharing a common pattern of FC abnormality. In other words, when connectomes from individuals with ASD differ from those of controls, they differ idiosyncratically. This suggests that successful biomarkers will require employing and developing analytic techniques sensitive to idiosyncratic (but stable) neural presentations.

2 **182.002** Action Observation Modulates Mirror Neuron System in Toddlers and Preschoolers with and without Autism Spectrum Disorders

***M. A. Krol**, J. Leano, H. Tager-Flusberg and D. Plesa-Skwerer, Psychological and Brain Sciences, Boston University, Boston, MA*

Background:
Action execution and observation lead to activation of the mirror neuron system (MNS). This system is hypothesized to be fundamental to social cognition. However, little is known about the development of the MNS, especially the functioning of this system in toddlers and preschoolers, the stage when communication skills are rapidly developing. Given that children with autism spectrum disorders (ASD) start to show clear signs of social deficits in this period, an important question is whether ASD is linked to impairments in the MNS that can be detected at this age.
Objectives:
The aim of the study was to compare neurophysiological activation during action observation and execution in the MNS between young children with and without ASD. Furthermore, we investigated whether observation of an action that is more relevant in social contexts (i.e. pointing) modulates the MNS activity differently than a direct action (i.e. grasping).

Methods:
Participants
15 typically-developed (TD) young children (M = 42.3 months; range 25-59) and 6 young children with ASD (M = 37.0 months; range 24-48) participated and provided quality data. ASD diagnoses were confirmed on the ADOS-2 Toddler module or Module 1.

Stimuli and procedure
To measure activation of the MNS, electroencephalography (EEG) recordings were obtained using the EGI system during action execution and observation. Power in the 7-10 Hz frequency band at the sensorimotor areas (C3 and C4 in the 10/20 system), the mu rhythm, was used as an index for MNS activity. This was measured when the toddlers and preschoolers performed a right-handed grasping action and when they observed video clips of the same grasping action and a pointing action performed by an actor. Data were included if children provided a minimum of 10 trials for each of the three conditions, execute grasp, observe grasp and observe point.

Results:
As expected, both the TD and ASD groups demonstrated activation in left sensorimotor area when grasping an object. In the TD group, modulations of power in the mu rhythm were stronger when observing grasping actions than pointing actions. Responses were bilateral with stronger effects in the left hemisphere during the observation of a grasping action. In contrast, the young children with ASD exclusively demonstrated a significant effect in the right hemisphere during the observation of pointing but not for grasping.

Conclusions:
The findings of the present study show that toddlers and preschoolers with ASD appear to have a different activation pattern in the MNS during action observation. Since this system has been proposed to play a crucial role in social development, impairments in the MNS could explain some of the deficits in social and communication abilities. The current study shows that this relation is already present at an early age, which could lead to new approaches in early intervention designed to improve the functioning of the MNS.

3 **182.003** Adolescents and Young Adults with Autism Spectrum Disorder Show Differences in Dynamics and Recruitment of Cognitive Control Networks

***M. Solomon**[1,2,3], M. K. Krug[4], C. C. Coleman[4], M. V. Elliott[5], J. Hogeveen[6], T. A. Niendam[7], J. D. Ragland[7] and C. S. Carter[8], (1)MIND Institute, Sacramento, CA, (2)Imaging Research Center, UC Davis, Sacramento, CA, (3)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (4)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA, (5)Department of Psychology, University of California, Berkeley, Berkeley, CA, (6)Department of Psychiatry & Behavioral Sciences, UC Davis, Sacramento, CA, (7)Imaging Research Center, Sacramento, CA, (8)Department of Psychiatry and Behavioral Sciences, University of California Davis, Sacramento, CA*

Background:
Individuals with Autism Spectrum Disorder (ASD) exhibit cognitive control (CC) deficits that appear to persist into adolescence and adulthood (Ozonoff et al, 1991, Solomon et al, 2017). CC deficits may be associated with the difficulties in social functioning, adaptive functioning and restricted and repetitive behaviors that are characteristic of individuals with ASD. Previous fMRI studies with slow event-related versions of the preparing to overcome prepotency (POP) task found evidence that typically developing (TYP) individuals develop a mature LPFC/parietal network in adolescence; however, individuals with ASD may continue to rely more heavily on a less mature dACC/LPFC network when presented with a situation that requires the implementation of CC (Solomon et al, 2009, Solomon et at, 2014).

Objectives:

(1) Investigate potential group differences in CC by looking at behavioral performance in a rapid event-related version of the POP task in participants aged 12-22 years old. (2) Associate behavioral measures with recruitment of brain regions known to play a role in implementation of CC. (3) Examine age-related changes in CC network recruitment and connectivity.

Methods:

Participants included 46 ASD (mean age=17.2 years; mean IQ=103) diagnosed using gold standard measures and 46 TYP (mean age=16.7 years; mean IQ=109). They completed four 28 trial runs of the Rapid Preparing to Overcome Prepotency (rPOP) task in the fMRI environment. For each trial of rPOP, a color cue was presented, followed by an arrow probe. For green cues, participants were instructed to press a button on the same side as the arrow probe. For red cues, participants were instructed to press a button on the opposite side of the arrow. Data was acquired using a 3 Tesla Siemens Tim Trio with a 32 channel head coil. Data were preprocessed and analyzed using SPM12. Functional connectivity analyses used CONN toolbox (http://www.nitrc.org /projects/conn).

Results:

Behavioral performance was assessed by calculating inverse efficiency score (IES; RT(ms)/accuracy; larger values indicate inefficient performance).There was a main effect of both cue type and diagnosis and a significant cue type X diagnosis interaction (F=10.17,p<.005), indicating that the ASD group was less efficient at the task. Whole brain analysis indicated that recruitment of BA 32 was greater for red cue trials compared to green cue in both groups (p-FDR<.05). In the ASD versus the TYP group, there was significantly stronger functional connectivity between the dACC and the DLPFC at the cue phase (Figure 1), which was negatively associated with task performance (Figure 2). This connectivity pattern negatively correlated with age in TYP, but there was no relationship in ASD.

Conclusions:

Our findings suggest a possible neural mechanism underlying the CC impairment evidenced by poor behavioral performance in ASD on the rPOP task. The developmental dissociation between TYP and ASD in this consequential network is also of great interest, and may provide an explanation for the persistence of CC deficits into young adulthood in ASD. Future analyses will investigate how these CC networks develop longitudinally, and their relationships to relevant clinical and adaptive functioning outcomes in young adults with ASD.

182.004 Age-Related Differences in the Large-Scale Resting State Executive Network and Relationships with Social Communication Impairments in Autism Spectrum Disorder

M. Walsh[1]*, L. C. Baxter*[2]*, C. J. Smith*[3] *and B. B. Braden*[4]*, (1)Arizona State University, Tempe, AZ, (2)Radiology, Barrow Neurological Institute, Phoenix, AZ, (3)Southwest Autism Research & Resource Center, Phoenix, AZ, (4)College of Health Solutions, Arizona State University, Tempe, AZ*

Background: The first children diagnosed with autism spectrum disorder (ASD) are now elderly; yet, there is little research on aging in adults with ASD. Abnormalities observed in resting-state functional connectivity (rs-FC) of large-scale brain networks are thought to underlie ASD symptoms. The rs-FC of these networks also declines with normal aging, most strongly in the executive network (EN). This is concerning for aging adults with ASD, since executive functioning has been postulated as a compensatory domain responsible for ameliorating the core symptom, social communication impairments (SCI), in ASD.

Objectives: We aimed to determine age-related differences in EN rs-FC in adults with ASD versus neurotypical (NT) adults. Additionally, we aimed to determine age-related differences in SCI, and the relationship between EN rs-FC and SCI, in adults with ASD. We hypothesized adults with ASD would experience larger age-related changes in EN rs-FC than NT adults. Further, we hypothesized middle-age adults with ASD would have greater SCI and a stronger relationship between SCI and EN rs-FC, than young-adults with ASD.

Methods: Participants were 24 young adult (YA; 18-25 years) and 25 middle-aged (MA; 40-64 years) adult males with high-functioning ASD, and 15 YA-NT and 21 MA-NT adult males. Differences in SCI (measured by the Social Responsiveness Scale -2; SRS-2) between YA and MA adults with ASD were evaluated with a t-test (p<0.05, one-tailed). We used independent component analysis to generate whole-brain rs-FC maps of the EN for all participants. Whole-brain EN comparisons were made using a two-factorial design in Statistical Parametric Mapping-12 and small-volume correction (p<0.05, false discovery rate) using an EN mask (neurosynth.org). An exacerbated aging trajectory of rs-FC decline in ASD was probed with a contrast matrix modeling reduced rs-FC in ASD participants relative to NT participants, and a larger age-related decline between ASD age groups than NT age groups. Rs-FC of six neo-cortical EN nodes was extracted and correlations with SCI were investigated in MA-ASD and YA-ASD groups separately (p<0.05, family-wise error corrected). IQ was entered as a covariate in all analyses.

Results: Although MA-ASD participants demonstrated higher SCI than YA-ASD, this difference was non-significant (p=.13). The EN demonstrated exacerbated age declines in rs-FC of the bilateral dlPFC, with only the left hemisphere surviving statistical correction. Lastly, there was a significant negative correlation between rs-FC of the right dlPFC and SCI in MA-ASD but not YA-ASD participants.

Conclusions: In one of the first aging rs-FC investigations in adults with high-functioning ASD, our findings suggested exacerbating age-related hypoconnectivity in frontal regions of the EN, relative to NT adults. Further, EN hypoconnectivity was related to increased SCI in middle-age adults with ASD only. Findings provide some of the first insights of brain mechanisms underlying core symptoms in older adults with ASD.

182.005 Atypical Neural Response to Biological Motion in Children with ASD: A Preliminary Functional Near Infrared Spectroscopy Analysis

A. Atyabi[1]*, M. Kim*[2]*, B. Li*[3]*, E. Barney*[4]*, Y. A. Ahn*[2]*, M. C. Aubertine*[5]*, S. Corrigan*[2]*, E. Neuhaus*[6]*, K. Pelphrey*[7] *and F. Shic*[4]*, (1)Seattle Children's Research institute University of Washington, Seattle, WA, (2)Seattle Children's Research Institute, Seattle, WA, (3)Computer Science and Engineering, University of Washington, Seattle, WA, (4)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (5)Seattle Children's Hospital and Research Institute, Seattle, WA, (6)Seattle Children's Hospital, Seattle, WA, (7)Autism and Neurodevelopment Disorders Institute, George Washington University and Children's National Medical Center, Washington, DC*

Background:

Attentional bias towards biological motion (BM) is an evolutionarily-preserved early-developing skill considered a fundamental process of neurocognition (Krakowski, 2014). It is likely that perceptual sensitivities underlying preferences for social and biological information impact and underpin developmental trajectories of social cognition skill acquisition, an area of primary deficits in individuals with ASD. Recognition of and preference for BM is found to be impaired in ASD (e.g. Kaiser et al. 2009, 2010, Annaz et al. 2012), with oxytocin and social inclusion modulating perceptual and neurophysiological response to BM in typical individuals (Keri and Benedek 2009, Perry et al. 2010, Bolling et al. 2014). Bolling et al. (2014), in a dual fMRI-fNIRS (functional Near Infrared Spectroscopy) study of 12 healthy typically developing (TD) adults demonstrated that fNIRS can reliably measure brain responses to BM. However, there are few reported studies of BM using fNIRS in young children with ASD.

Objectives:

To explore the use of fNIRS to examine hemodynamic response differences in TD children and children with ASD as they viewed emotion-modulated BM stimuli.

Methods:

8-year-old children with ASD (n=40) and TD (n=25) sat in front of a computer monitor while wearing a cap embedded with optodes (Gowerlabs NTS) covering prefrontal cortex (PFC) and superior temporal sulcus (STS) areas. Emotional BM clips (fear, anger, joy, neutral) were presented alongside rotating control point light displays (PLDs). Changes in oxygenated hemoglobin (Oxy-Hb) during stimuli observation were analyzed by applying motion artifact removal, band pass filtering (0.010hz-0.50hz) and General Linear Modeling (for short separation and drift correction). Long distance channels were removed to reduce artifactual and noisy signal.

Results:

a) Trial-based analysis: using the median of the 90th percentile concentration from valid trials in each channel, statistical analyses revealed the following: **1) Biomotion:** Between-group differences in Oxy-Hb (t-test, α=0.05**)** over the *angular right gyrus* and deOxy-Hb(α=0.05) over *frontal_middle_left*, *frontal_inferior_triangularis_left,* and *angular_left* areas. **2) Rotation**: Only weakly significant differences (α=0.1) were observed between TD and ASD participants with Oxy-Hb over *frontal_supramarginal_left, frontal_middle_left,* and *parietal_inferior_right* and with deOxy-Hb over *frontal_supramarginal_left*.

b) Functional-Connectivity: the analysis of functional connectivity with 0.65 cross correlation cutoff indicated higher PFC connectivity in TD compared to ASD in Oxy-Hb, with TD participants demonstrating both inter- and intra-hemispheric connectivity in frontal regions both in rotation and biomotion stimuli. TD participants demonstrated higher level of intra-connectivity with the rotation paradigm compared to biomotion while a similar level of inter-connectivity in frontal regions was observed in this group in both biomotion and rotation paradigms. No intra-connectivity was observed in middle and posterior regions with either biological motion or rotation in either group.

Conclusions:

While analyses are ongoing, preliminary results suggest that between-group differences are evident in brain areas associated with biological motion perception in typical individuals and noted in previous research to be atypically activated in children with ASD. Functional connectivity results suggest that responses of children with ASD to biological motion are less expansively organized across brain regions than TD children, who demonstrated a wider breadth of activity and connectivity across the frontal areas.

182.006 Autism Symptom Severity Predicts Accuracy of Facial Emotion Recognition Under Conditions of Low Theta-Power Early in Visual Processing

C. Halpern[1]*, T. Clarkson*[2] *and M. D. Lerner*[3]*, (1)Psychology, Stony Brook University Dept. of Psychology, Stony Brook, NY, (2)Psychology, Temple University, Philadelphia, PA, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background: Individuals with autism spectrum disorder (ASD) demonstrate deficits in facial emotion recognition (FER; Harms et al., 2010), which requires holistic visual processing (Duchaine et al., 2006). The weak central coherence model (WCC) predicts that individuals with ASD have deficits in holistic processing (Happé and Frith, 2006). While, the level of impairment on FER tasks generally relates to ASD symptom severity (SS) (Spencer & O'Brian, 2006; Humphreys et al., 2007), some individuals with high ASD SS can have intact performance on FER task, possibly through the engagement of compensatory neural processes that don't involve holistic processing (Harms et al, 2010). However, different neural processes that reflect cognitive compensation during FER task have yet to be identified in individuals with ASD. One possible neural correlate of holistic processing that might shed light on this question is early posterior theta activity. Early Posterior theta in visual processing task can be measured during the P100 event-related potential (ERP) and is associated with cognitive integration during visual working memory tasks (Sauseng et al., 2009), and abnormalities in theta are associated with deficits in object recognition and memory in individuals with ASD (Chan et al., 2011). The extent to which ASD SS relates to FER, as a function of early posterior theta, has yet to be examined. This interaction can clarify the possible compensatory neural processes utilized by individuals with ASD, and is important for understanding the heterogeneity in FER.
Objectives: We examine whether ASD SS predicted performance on a FER task and if this relation varied as a function of early theta-power during the P100 ERP window.

Methods: Fifty-three youth (M_{age}=11.60, SD_{age}=2.96; 38 male) with IQ≥70 (M_{IQ}=103.49, SD_{IQ}=15.40) and ADOS-2-confirmed ASD diagnosis and SS. Electroencephalography (EEG) data were recorded during a FER task (DANVA-2; Nowicki, 2004). Natural log transformed theta power at the P100 ERP was calculated using wavelet analysis for central frequencies 4-7.5Hz using 20 logarithmic steps at 4 cycles. Moderated linear regression analyses were used to test the relation of ASD SS and accuracy for identifying adult and child emotional faces at varying levels of the theta frequency during the P100.

Results: No correlations between ADOS SS and FER performance, theta-power and FER performance, or theta-power and SS (p's> 0.26) were found. However, a significant interaction was found between SS and P100 theta-power in predicting FER performance (*B*= 0.463 p = 0.026), such that at lower levels of theta-power and greater SS predicted *better* FER performance (Figure 1).

Conclusions: Our results suggest that greater SS predicts *better* FER performance, but only among those exhibiting lower occipital theta-power during the P100 ERP window. Heightened posterior theta is associated with holistic processing during FER tasks (Sauseng et al., 2009). These results suggest that, when such holistic processing is not engaged, individuals with greater symptoms of ASD may utilize alternate or compensatory strategies to decode faces, while those with fewer symptoms may rely on underdeveloped holistic processing abilities. Our results may help explain heterogeneity in relations between ASD SS and FER performance.

182.007 Autism-Associated 16p11.2 Microdeletion Impairs Prefrontal Functional Connectivity in Mouse and Human

A. Bertero[1]*, A. Liska*[1,2]*, R. Parolisi*[3]*, M. Esteban Masferrer*[4]*,* ***M. Pagani***[1,2]*, M. Gritti*[5]*, M. Pedrazzoli*[6]*, A. Galbusera*[1]*, A. Sarica*[7]*, A. Cerasa*[7]*, M. Buffelli*[6]*, R. Tonini*[5]*, A. Buffo*[3]*, C. Gross*[4]*, M. Pasqualetti*[1] *and A. Gozzi*[1]*, (1)Istituto Italiano di Tecnologia, Functional Neuroimaging Lab, Centre for Neuroscience and Cognitive Systems, Rovereto, Italy, (2)University of Trento, CIMEC, Rovereto, Italy, (3)University of Turin, Neuroscience Institute Cavalieri Ottolenghi (NICO), Department of Neuroscience Rita Levi-Montalcini, Torino, Italy, (4)European Molecular Biology Laboratory (EMBL), Mouse Biology Unit, Monterotondo, Italy, (5)Istituto Italiano di Tecnologia, Neuroscience and Brain Technologies Department, Genova, Italy, (6)University of Verona, Department of Neurosciences, Biomedicine and Movement Sciences, Verona, Italy, (7)Consiglio Nazionale delle Ricerche, Catanzaro, Italy*

Background: Abnormal brain connectivity has been repeatedly observed in autism spectrum disorder (ASD) patients. However great heterogeneity exists in the manifestation of these aberrancies, and little is known on the role of specific ASD-associated mutations in affecting brain functional coupling. Human chromosome 16p11.2 microdeletion, a trait associated to mild intellectual disability, is one of the most common gene copy number variation (CNV) in autism, accounting for approximately 0.5-1% of all ASD cases.

Objectives: Here we sought to causally probe a role of 16p11.2 CNV in affecting brain connectivity. To this purpose, we mapped resting-state connectivity in children with 16p11.2 deletion and in a mouse carrying an orthologous 16p11.2 deletion (Horev et al., 2011). To mechanistically probe the observed connectional impairments, we also performed electrophysiological and viral tracing mapping in 16p11.2 mouse mutants.

Methods: Human resting-state fMRI (rsfMRI) imaging was performed on 3T Siemens scanner on a previously characterized sample of 16p11.2 del carriers and control subjects from the Simons VIP consortium. Control of motion artefacts was achieved via data scrubbing at a FWD=0.5 mm, regression of motion traces, and by retaining subjects with > 80% of initial fMRI frames. All mouse fMRI images were acquired on adult male 16p11.2$^{+/-}$ mutants and control littermates on a 7.0 Tesla MRI scanner (Bruker Biospin) under light halothane sedation, and images were analysed as described in Liska et al., 2017. *In-vivo* LFP were recorded by placing electrodes in anterior cingulate and retrosplenial regions. Quantification of retrogradely labelled cells was carried out with rabies virus injection as previously described (Liska et al., 2017).

Results: Inter-group connectivity mapping revealed reduced long-range prefrontal rsfMRI connectivity in human 16p11.2 del carriers (A-B), an effect robustly associated with increased social responsiveness scale (C-D). We also observed foci of reduced connectivity in temporal and parietal areas involved in sociocognitive functioning. To bolster a role of 16p11.2 CNV in affecting prefrontal connectivity, we used resting-state fMRI to map functional connectivity in a mouse line harbouring a deletion in orthologous regions to 16p11.2. In keeping with human findings, 16p11.2$^{+/-}$ mice exhibited reduced long-range prefrontal connectivity (E-F). 16p11.2 mutants also presented impaired long-range neural synchronization in the delta frequency range, corroborating a neural origin for the observed connectivity impairment (G-H). Retrograde axonal labelling in 16p11.2$^{+/-}$ mutants revealed altered neuronal density in prefrontal-projecting thalamic-nuclei, suggesting a possible contribution of thalamo-frontal miswiring to the observed connectivity impairment (I-L).

Conclusions: Our data document converging prefrontal connectivity impairments in human 16p11.2 del carriers and in a mouse with the same genetic deficit. We also show that 16p11.2 deletion in the mouse results in aberrant thalamo-frontal wiring and impaired long-range low-frequency neural synchronization. These findings establish a link between a common ASD-associated CNV and macroscale connectional aberrancies. They also suggest that 16p11.2 del can predispose to neurodevelopmental disorders and impaired socio-cognitive function via a dysregulation of long-range prefrontal connectivity.

182.008 Children with Autism Show No Leftward Asymmetry of Neural Response to Native Vs. Nonnative Speech Distinction

L. Yu[1,2], *X. Wu*[3], *S. Wang*[2], *D. Huang*[3] *and Y. Zhang*[1,4], *(1)Department of Speech-Language-Hearing Sciences, University of Minnesota, MINNEAPOLIS, MN, (2)Psychology, South China Normal University, Guangzhou, China, (3)Guangzhou Rehabilitation & Research Center for Children with ASD (Guangzhou Cana School), Guangzhou, China, (4)University of Minnesota Center for Neurobehavioral Development, MINNEAPOLIS, MN*

Background: The left hemisphere plays a dominant role in linguistic processing (Zatorre & Gandour, 2008). Leftward lateralization has been found to develop in parallel with children's advance in linguistic competence (Mills et al., 2004). Similarly, native speakers of a specific language show greater neural sensitivity and efficiency in processing the auditory patterns found in that language (Kuhl, 2010; Zhang et al., 2005). However, such neural specialization appears to be significantly deviated in children with autism. Toddlers with autism failed to show leftward asymmetry when listening to natural speech (Eyler et al., 2012); children with autism show reduced neural sensitivity in discriminating phonological units in the native language but not so much in discriminating non-phonological units and nonspeech contrasts (Huang et al., 2017; Wang et al., 2017; Yu et al., 2015). These findings all point to an altered language-specific neural specialization in children with autism.

Objectives: The current study aimed at examining the neural coding of native vs. non-native phonological processing in children with autism. By comparing native vs. nonnative responses, we expected to investigate the functional specialization in detecting abstract word-level phonological structure of the native language.

Methods: EEG was recorded from 21 school-age (9~13 years) native Chinese-speaking children with autism and 25 age-matched TD controls. The participants were instructed to watch a self-chosen cartoon while ignore any sounds. The native condition consisted of a sequence of Chinese disyllabic nonsense words (e.g., /gu4bo1/), and the nonnative condition included a list of English disyllabic nonsense words (e.g., goober). The stimuli in the two conditions were matched by number of syllables, phonemic units (e.g., CVCV) and key acoustic features (i.e., duration, overall intensity). Mean ERP response amplitude was measured on the left side (F3/C3) and right side (F4/C4) of the scalp, within the time windows of 200-400, 400-600, and 600-800 ms.

Results: Regardless of stimulus and hemisphere, the autism group had smaller response amplitude than the TD group in the two later time windows but not the early window. Both groups showed larger ERP negativity to the native stimuli than to the nonnative stimuli. Specifically, In the 200-400 and 600-800 ms windows, the ERP difference in the TD group was restricted to channels on the left side, whereas the difference in the autism group was bilaterally distributed. In the 400-600 ms window, the ERP difference was mainly driven by the autism group with the effect only on the right side.

Conclusions: Both children with autism and TD children differentiate the abstract phonological structures of native vs. nonnative speech at the neural level. The ERP differences in the TD children show a clear leftward distribution, which coincides with existing adult data that linguistic information in native speech can engage specialized neural network for language (Perrachione et al., 2009). In comparison, the lack of leftward asymmetry in autism might represent a neural signature of impaired or delayed neural specialization for native language processing. Data from nonspeech stimuli are needed to examine the role of prosody in such language-specific neural specialization.

182.009 Cortical Inhibitory Alterations in Autism Spectrum Disorders: A TMS Study

I. Bernardino[1,2], *A. Dionísio*[3], *R. Monteiro*[3], *I. Violante*[4] *and M. Castelo-Branco*[5,6], *(1)Institute for Nuclear Sciences Applied to Health (ICNAS), Coimbra, Portugal, (2)IBILI - Institute for Biomedical Imaging and Life Sciences, Faculty of Medicine – University of Coimbra, Portugal, Coimbra, Portugal, (3)Institute of Nuclear Sciences Applied to Health, University of Coimbra, Coimbra, Portugal, (4)School of Psychology, Faculty of Health and Medical Sciences, University of Surrey, London, United Kingdom, (5)CIBIT & IBILI - Institute for Biomedical Imaging and Life Sciences, Faculty of Medicine – University of Coimbra, Portugal, Coimbra, Portugal, (6)ICNAS - Produção Unipessoal Lda, Coimbra, Portugal*

Background: Autism spectrum disorder (ASD) is a pervasive neurodevelopmental condition of considerable relevance in cognitive and clinical neuroscience because of its intriguing combination of symptoms, including marked impairments in social interaction and communication in the presence of repetitive stereotyped behavior. Although several studies have characterized the ASD phenotype, the nature of its pathophysiology remains unclear. Emerging evidence suggests that inhibitory GABA neurotransmission represents an important dysfunctional pathway in ASD. This led us to investigate whether alterations in the push-pull mechanism between physiological excitation and inhibition may be present in ASD and likely conduct to altered motor cortical excitability.

Objectives: We aimed to probe whether there are alterations in cortical excitability, including inhibition and facilitation, in the primary motor cortex (M1) on ASD patients, via the use of transcranial magnetic stimulation (TMS) well stablished protocols: paired-pulse (pp-TMS), input/output curves (I/O) and cortical silent period (CSP).

Methods: Data were acquired from 8 high-functioning (mean full-scale IQ 105) ASD patients (mean age ± SE = 21.56 ± 1.27) and 5 chronological age and full-scale IQ-matched control participants (mean age ± SE = 24.83 ± 1.54).

In pp-TMS, two magnetic pulses are applied, separated by variable inter-stimulus intervals (ISI) which can be associated to either cortical excitation or inhibition. Three protocols were implemented: short-interval intracortical inhibition (SICI) measuring cortical inhibition putatively mediated by GABAA receptors (ISIs= 1, 3, 5ms); intracortical facilitation (ICF) reflecting a mixture of excitatory (NMDA glutamate) and inhibitory (GABAA) effects (ISIs=10, 15, 20ms); and long-interval intracortical inhibition (LICI) showing inhibition mediated by GABAB receptors (ISIs= 50, 100, 150ms).

In I-O curve, TMS intensities at 90, 100, 110, 120, 130 and 140% of RMT were used. Ten pulses at each intensity were delivered in a randomized order.

Regarding CSP, a suprathreshold TMS pulse is given during voluntary muscle contraction producing a motor-evoked potential (MEP) followed by a period of EMG silence. Measures were obtained while participant maintained contraction of 20% of the maximal force, measured with a dynamometer. Ten CSPs were recorded using an intensity of 130% of RMT.

Results: Our preliminary results showed significant differences between groups regarding both relative and absolute cortical silent period measures. ASD patients revealed longer relative (M=159.75, SE=8.60) and absolute periods (M=117.11, SE=8.22) than controls (relative: M=129.45, SE=9.61; absolute: M=87.60, SE=9.04) (t-test; p=.038 and p=.034, respectively). Concerning paired-pulse, no significant differences were yet found (while we predict power to increase when additional participants are added), although a trend for higher values in ASD was shown for the 5ms interval, in SICI (t-test, p=.089). In the IO protocol, participants did not differ regarding curve slope, maximum MEP and S50, i.e. the stimulus intensity that produces a MEP amplitude of 50% of the maximum.

Conclusions: In this study, we found preliminary evidence of altered motor cortical excitability in ASD which seems to involve intracortical inhibitory pathways. These results are in line with previous findings reporting altered GABA neurotransmission in this pathology and suggest altered GABA-mediated cortical inhibition which possible underlies cognitive impairments present in ASD.

10 **182.010** Decreased Rest Cerebral Blood Flow (CBF) in the Superior Temporal Sulcus (STS) in Children with Autism: An MRI-ASL Study

A. Saitovitch[1], *E. Rechtman*[2], *H. Lemaitre*[3], *J. M. Tacchella*[4], *N. Chabane*[5], *A. Philippe*[6], *E. A. Douard*[7], *H. Guemar*[4], *A. Vinçon-Leite*[8], *A. Cavalcanti Ferreira*[9], *R. Gobbo*[9], *R. Calmon*[4], *D. Grevent*[4], *F. Brunelle*[6], *N. Boddaert*[10] *and M. Zilbovicius*[4], *(1)INSERM, Paris, France, (2)INSERM U1000, Institut Imagine, Paris, France, (3)Inserm U1000, institut Imagine, Université Paris Sud, Paris, France, (4)Inserm U1000, institut Imagine, Paris, France, (5)CHUV, Lausanne, Switzerland, (6)Necker Hospital, Paris, France, (7)Research Center of UHC Sainte-Justine, Montreal, QC, Canada, (8)INSERM U1000, Paris, France, (9)Inserm U1000, institut Imagine, UNICAMP, Paris, France, (10)Hospital Necker, Paris, France*

Background: The first results on brain rest functional abnormalities in ASD using positons emission tomography (PET) have described decreased cerebral blood flow (CBF) in children with ASD compared to controls in the temporal regions and particularly in the superior temporal sulcus (STS) (Zilbovicius et al., 2000; Ohnishi et al., 2000). In addition, multivariate classification analysis has shown that STS hypoperfusion allows to correctly classify individual images of children with ASD at rates of 86% (sensitivity: 88%, specificity: 75%) (Duchesnay et al., NeuroImage, 2011). This suggests that the decrease in CBF at the STS level predicts the diagnosis of autism in 86% of cases and could therefore become a useful biomarker in autism. However, PET has significant limitations such as injecting radioisotope products, which makes it unsuitable to study children. Nowadays it is possible to measure rest CBF using arterial spin labeling (ASL) sequence in MRI, without contrast nor radioactivity injections. Thus, ASL could replace the PET method, which had important limitations.

Objectives: To reproduce the results described with PET using ASL-MRI in order to develop a possible biomarker in autism using a non-invasive brain imaging method.

Methods: Twelve children with ASD (age = 11.2 ± 3 years, 7-16 years) and 28 typically developing (TD) children (age = 10.1 ± 2.5 years) participated in this study. The ASD diagnosis was based on DSM-IV and the ADI-R. All participants underwent MRI at the Pediatric Radiology Department at Necker Hospital, in Paris, and rest CBF measures were performed with the ASL sequence, which allows rest CBF measures based on marking arterial water spin. Image processing was performed using Statistical Parametric Mapping 8 (SPM8) (http://www.fil.ion.ucl.ac.uk/spm). A voxel-to-voxel analysis on the whole brain and without a priori hypothesis was performed comparing the ASL images of children with ASD to the control group of children. Further region of interest (ROI) analyses was performed on the bilateral superior temporal regions.

Results: Whole brain voxel-by-voxel analysis showed a significant decrease in rest CBF ($p < 0.05$ FEW corrected for multiple comparisons) in the ASD group compared to the TD group in the left posterior STS. In addition, ROI analysis showed decreased rest CBF in children with ASD in left and right superior temporal regions.

Conclusions: The evidence of a decreased rest CBF within the STS by a non-invasive imaging MRI method could have a major impact on understanding the pathophysiological mechanisms underlying autistic behavior. In addition, if confirmed in a larger sample, STS hypoperfusion may become a biomarker in ASD for the evaluation of new therapeutic strategies.

11 **182.011** Differences in Frontal-Posterior Activity during Mental Rotation of Body-Related Stimuli in Autism Spectrum Disorders

J. A. Trapani[1], *H. M. Wadsworth*[2] *and R. Kana*[3], *(1)University of Alabama at Birmingham, Birmingham, AL, (2)UAB School of Medicine, Birmingham, AL, (3)University of Alabama, Birmingham, Birmingham, AL*

Background: Cognitive and behavioral studies in recent years have identified visuospatial processing as a generally intact area of functioning in individuals with autism spectrum disorders (ASD). Previous research suggests that this advantage may be reflected in tasks, such as mental rotation. However, mental rotation of body-related stimuli in ASD has received little attention relative to rotation of objects and shapes.
Objectives: This study investigates (a) the neural mechanisms underlying mental rotation of sensorimotor stimuli and (b) the extent to which autistic traits and symptomology play a role in processing mental rotation.

Methods: Thirteen children and adolescents with ASD and 15 age-and-IQ-matched typically developing (TD) control participants took part in this fMRI study. Participants completed a mental rotation task while fMRI data were acquired using a Siemens 3.0 Tesla Allegra head-only scanner. In this task, images of two hands appeared on a computer screen, one on the left and one on the right side of a crosshair. Participants were asked to press a button if the rotated hand on the right panel (rotated either 45° or 90°) was the same hand as the hand shown on the left panel. Imaging analysis included brain activation, change in percent signal intensity, and functional connectivity, along with correlation analyses involving these measures and behavioral assessment and self-report scores.

Results: Preliminary analyses indicate that the ASD group was significantly more accurate, relative to TD group, in mental rotation [$F(1,696) = 31.75$, $p<0.01$], although this effect was related to their spatial skills, measured by performance IQ. When 45° rotation was contrasted with that of 90° rotation, the ASD group showed greater activation, relative to TD group, in the right fusiform gyrus (FG), left and right middle occipital lobe, and right precuneus. The TD group, on the other hand, showed greater activation in left inferior frontal gyrus (LIFG), left medial prefrontal cortex (MPFC), left supplementary motor area (LSMA), and left anterior cingulate cortex (ACC) ($p<0.005$, k=144). ASD participants also showed intact functional connectivity during this mental rotation task.

Conclusions: While participants with autism performed the mental rotation task as well as or better than the TD controls, it was accompanied by differences in brain activity. The ASD participants seem to have relied more on visuospatial and body related areas (increased activity in FG, occipital, and precuneus), whereas TD participants recruited frontal areas (increased activity in MPFC, SMA, LIFG). It is possible that there is strategic difference between the groups in approaching this task, perhaps bottom-up versus top-down processing. This variation in approach may underlie difficulties observed in individuals with ASD when faced with more complex social stimuli requiring visual-perspective taking or full-body rotations and warrants continued and future investigations.

12 **182.012** Distinct Functional Network Connectivity in Children with ASD, ADHD, and OCD: Data from the Pond Network

M. M. Vandewouw[1]*, E. J. Choi*[2]*, J. P. Lerch*[3]*, M. J. Taylor*[4] *and E. Anagnostou*[2]*, (1)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada, (4)The Hospital for Sick Children, Toronto, ON, Canada*

Background: Children with autism spectrum disorder (ASD) share genetic vulnerability and symptom domains with other neurodevelopmental disorders (NDs), such as attention-deficit/hyperactivity disorder (ADHD) and obsessive-compulsive disorder (OCD) despite distinct diagnostic criteria. A body of research of resting-state functional connectivity for each of the disorders shows that NDs exhibit some notable overlapping patterns of atypical functional connectivity in large-scale networks. However, the findings have been inconsistent across studies and there is no study to consider three different NDs within a single cohort. We compared large-scale whole brain fMRI networks directly across ASD, ADHD, OCD, and typically developing (TD) participants collected in a single cohort using graph theory to examine what the shared and disorder-specific functional organization abnormalities are in the three different NDs.
Objectives: We investigated a) if resting-state functional connectivity differs between NDs (including children with ASD, ADHD, and OCD) and TDs, and b) if the children with ASD show different functional connectivity profiles compared to children with ADHD or OCD.

Methods: The current study included 311 high-functioning children and adolescents (out of 354 subjects, excluding those with excessive motion), 156 with ASD, 68 with ASD, 43 with OCD, and 44 TDs (4-21 years of age, mean 12 years). T1-weighted and resting-state fMRI (5 minute duration) images were obtained on a Siemens 3T MRI using a 12-channel head coil. Subjects' T1-weighted images were parcellated into 82 cortical and subcortical ROIs, and subject-specific networks were constructed by correlating the mean resting-sate time-series for each ROI pair. Local (degree, strength, local efficiency, and betweenness centrality) and global (small-worldness and global efficiency) network measures were obtained for each network over a range of sparsity thresholds, and the area under the threshold curve (AUC) was calculated. An analysis of covariance was used to compare the network measure AUCs of NDs with TDs, as well as ASD with OCD and ADHD, with age and sex as covariates. Non-parametric permutation testing was used to determine significance ($p < 0.05$).

Results: Children with NDs showed an altered connectivity profile compared to the TDs, with increased degree and strength in ROIs including subcortical structures and the insula. These ROIs, as well as ROIs such as the pars opercularis and caudal anterior cingulate gyrus, also showed significantly increased local efficiency in NDs compared to TDs. Significant age and sex interactions were found between the two groups. Within the ND group, ASD exhibited significantly decreased degree and strength in ROIs including the paracentral gyrus compared to ADHD, while this effect was found in OCD in ROIs such as the fusiform gyrus. ASD also showed increased degree and strength in subcortical structures compared to OCD. Betweenness centrality also differed amongst the ND groups. Age and sex interactions differed significantly between the NDs; details will be presented.

Conclusions: The NDs show increased graph theoretic measures in subcortical structures compared to TDs. Within the NDs, we found evidence for distinct and shared areas functional connectivity in ASD, ADHD and OCD. These findings will help us understand the heterogeneity across NDs.

13 **182.013** EEG Abnormalities in Adolescents with ASD: A Power and Coherence Analysis

P. Wantzen[1]*, P. Clochon*[1]*, F. Doidy*[1]*, C. Piet*[1]*, C. Rebillard*[1]*, J. M. Guilé*[2]*, C. Mille*[2]*, F. Wallois*[2]*, F. Guénolé*[1,3]*, J. M. Baleyte*[1,3]*, F. Eustache*[1] *and B. Guillery-Girard*[1]*, (1)Normandie Univ, UNICAEN, PSL Research University, EPHE, INSERM, U1077, CHU de Caen, Neuropsychologie et Imagerie de la Mémoire Humaine, 14000 Caen, France, Caen, France, (2)Université de Picardie, INSERM, U 1105, CHU Amiens, groupe de recherches sur l'analyse multimodale de la fonction cérébrale, Amiens, France, (3)Service de Psychiatrie de l'Enfant et de l'Adolescent, CHU de Caen, Caen, France*

Background: Social and cognitive difficulties observed in autism could be partly explained by an atypical integration and perceptual processing associated with abnormalities in cerebral activity. Indeed, Resting-state electroencephalography (EEG) studies conducted in adults with Autism Spectrum Disorder (ASD) show a U-shaped model of power alteration with excessive power in low-frequency (delta and theta) and high-frequency bands (beta and gamma) contrasting with reduced alpha power. In addition, other EEG studies report altered brain connectivity with both hyper- and hypo-connectivity. In children with ASD, some results recently obtained do not fit with these models with for example and contrary to adults, reduced theta observed before 13 years old. Hence, modifications may occur after 13 years or during adolescence leading to adult models but there are too few studies conducted during this period to conclude.

Objectives: To specify cerebral particularities during resting state with high-density EEG, among adolescents with high functioning ASD aged from 10 to 18 years old compared to controls.

Methods: EEG was recorded in a sample of 17 adolescents with ASD compared to 27 age and IQ-matched typically developing adolescents. We examined eyes-closed and eyes-open EEG relative power and coherence in resting state for beta, theta, alpha and beta bands. Both short and long range functional connectivity was assessed with electroencephalographic coherence between pairs of electrodes in a high-density electrode array.

Results: We observed an important variability between participants for both relative power and coherence. We reported a U-shaped profile of relative power alterations in the ASD group compared to controls: delta, theta and beta relative power were increased and alpha relative power was reduced in adolescents with ASD. We also noticed long range hypo-connectivity from frontal to posterior regions for all band frequencies that contrasted with hyper-connectivity in posterior regions only for alpha band.

Conclusions: Our findings validate the U-shape profile in adolescents with ASD with increased power at low (delta, theta) and high (beta) frequencies and reduced alpha power. This profile of activity is associated with abnormal long range connectivity in all frequency bands that is consistent with difficulties in cognitive integration and regulation from anterior brain regions on posterior ones. In addition, we reported a posterior and short-range hyper-connectivity in alpha band. This excessive connectivity may participate to the atypical perceptual processing that characterizes ASD people. Further analysis combining EEG and behavioral data collected in this study will be crucial to identify EEG correlates of both perceptual and cognitive processing in adolescents with autism.

14 **182.014** EEG and Pupillary Response in Children with Autism: Results from the ABC-CT Feasibility Study

A. Naples[1], *F. Shic*[2], *A. R. Levin*[3], *R. Bernier*[4], *G. Dawson*[5], *M. Murias*[6], *S. Jeste*[7], *C. A. Nelson*[8], *S. Faja*[8], *K. Chawarska*[1], *C. Sugar*[7], *D. Senturk*[9], *G. Hellemann*[9], *J. Dziura*[10], *C. Brandt*[10], *S. J. Webb*[4] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Neurology, Boston Children's Hospital, Boston, MA, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (5)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (6)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)University of California, Los Angeles, Los Angeles, CA, (8)Boston Children's Hospital, Boston, MA, (9)UCLA, Los Angeles, CA, (10)Yale University, New Haven, CT*

Background: Dysregulated attention and arousal are comorbid features of ASD. These symptoms are associated with differences in noradrenergic activity. Pupil diameter (PD) is a marker of locus coeruleus (LC) activity, the primary cortical source of norepinephrine. Prior work has established that individuals with ASD exhibit attenuated pupil response to light. Despite the broad neuromodulatory efferents from the LC to cortex, there have been no studies in humans linking the dynamics of the pupillary light reflex (PLR) to EEG features; this relationship may help to parse heterogeneity among individuals with ASD and between ASD and controls.

Objectives: We examine: (1) the relationship of the PLR and EEG; (2) The relationship between PLR and individual alpha frequency (IAF); (3) the relationship of the PLR and EEG to clinical characteristics.

Methods: Data were collected from 25 children with ASD and 26 typically developing controls (TD) across five sites. Ages ranged from 4-11 years and IQ ranged from 53-133. Analyses were conducted on subsets of participants contributing valid PLR (ASD=23, TD=26), EEG (ASD=23, TD=26), and IAF data (ASD=21, TD=24). EEG data were recorded at 1000hz and spectral power was calculated from one second epochs. IAF was calculated from occipital electrodes in the range from 6-12hz. The PLR was calculated in response to a 133ms white flash followed by a black screen. PLR dynamics included relative constriction, latency of constriction, and redilation and constriction velocities.

Results: PLR comparisons revealed marginal differences in constriction velocity (t=1.941, *p*=.058), such that constriction velocity, but not latency, was faster in individuals with ASD than in controls. EEG analyses revealed individuals with ASD exhibited an atypical power spectrum; a less steep slope (t = 2.184, *p*=.034), and higher power in theta (t=2.5, *p*=.017), beta (t=2.638, *p*=.011), and gamma (t=2.91, *p*=.005) bands compared to controls. PLR latency correlated with theta (r=.374, *p*=.009), beta (r=.473, *p*<.001), and gamma power (r=.312, *p*=.031), and IAF correlated with PLR constriction (r=.295, *p*=.051) and constriction velocity (r=.326, *p*=.031). Among children with ASD, the ADOS calibrated severity score correlated with theta (r=.473. *p*=.023) and PLR latency (r=.359, *p*=.093). PLR latency also correlated with the socialization domain of the Vineland (r=-.586, *p* =.005). The Social Responsiveness Scale Cognition Subscale correlated with PLR constriction (r=-.459, *p*=.003). For all correlations, attenuated PLR response predicted elevated symptomology.

Conclusions: These are the first data to examine relationships between EEG and PLR within individuals with ASD, revealing potential relationships between brainstem nuclei, cortical activity, and clinical symptomology**.** The directionality of effects suggests that increased LC activity, indicated by increased PLR latency and attenuated constriction, is related to an atypical EEG profile and increased symptomology. Further analyses will parse shared and unique variance between PLR and EEG contributions to ASD symptomology and measures of EEG coherence. These findings show promise for the potential of these biomarkers as indicators of treatment response and as potential targets for treatment development.

15 **182.015** EEG Correlates of Face Processing in a Large ASD Sample

L. Mason[1], *E. J. Jones*[1] *and M. H. Johnson*[2], *(1)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (2)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom*

Background: Social and communicative impairments are a core feature of ASD, and behavioural impairments in face processing are commonly reported (Dawson et al, 2005). In order to understand whether these impairments reflect atypicalities in the neural circuitry underlying face perception, some researchers have used the high temporal resolution of EEG to investigate individual stages of face processing in ASD. Latency and amplitude differences of face-sensitive event related potential (ERP) components have been reported in adults (e.g. McPartland et 2011) and children (e.g. Webb et al, 2005) with ASD. Here we describe the results from the Longitudinal European Autism Project (LEAP), a component of the

EU-AIMS study.
Objectives: To characterise the nature and extent of atypicalities in EEG correlates of face processing in a large sample of individuals with ASD and age- and IQ-matched neurotypical controls.

Methods: Participants aged from 6-30 years of age watched 168 trials in which interleaved upright or inverted faces were presented, whilst their EEG was recorded. Data was centrally pooled, harmonised and segmented by trial, and artefacts were rejected. Neural responses to upright and inverted faces were averaged separately. The final analyses contain data from 496 individuals (271 with ASD).

Results: ERP responses to upright faces had slower latencies in ASD, but overall did not differ in amplitude. The effect of inversion was absent in children with ASD; the inversion effect emerged in adolescence and adulthood, but with a reduced magnitude compared to neurotypical controls. Face-sensitive ERP components were lateralised to the right hemisphere in both groups.

Conclusions: Longer ERP peak latencies suggests slower and/or less efficient processing of faces in ASD, from childhood to adulthood. An absence of an inversion effect in children with ASD, and a reduction in its magnitude in adolescence and adulthood, is suggestive of reduced cortical specialisation for faces. This may result from a lack of motivation to attend to other people, leading to the slower development of expertise for faces across development in ASD.

16 **182.016** EEG Correlates of the Attentional Blink: Relationship to Autism Symptoms

E. A. Kaplan*, N. Russo, J. Kopec, E. P. McKernan, E. L. Koelmel and A. M. Prawl, Psychology, Syracuse University, Syracuse, NY*

Background:
In light of findings of superior temporal visual search abilities in individuals with autism spectrum disorders (ASD), we sought to understand neurophysiological mechanisms underlying single-target search and its relationship to the attentional blink (AB). The AB is a phenomenon whereby the second of two targets is frequently missed when it occurs within 200-500 milliseconds (ms) of the first.

Objectives:

There were three main objectives to this study. First, to examine characteristics of the AB in children with ASD and IQ- and age-matched comparison children. Second, to assess the relationship between electrophysiological responses to single color-bound targets and a color-binding AB task in both groups. Third, to assess the relationship between electrophysiological responses and diagnostic criteria for ASD.

Methods:

15 children with ASD (mean age = 11.8 years; mean IQ = 102.7) and 15 IQ- and age-matched comparison children completed an AB color-binding task in which they were asked to identify two purple targets amongst black distractors. Participants also completed a single-target version of this task while electrophysiological responses were recorded. Variables of interest included the accuracy of identifying the first target (T1), the accuracy of identifying the second target given that the first target was identified (T2|T1), the AB depth, and properties of the N2pc and P3 ERP components.

Results:

Analysis of the AB tasks revealed no group differences in target detection accuracy, or in the depth of the AB. ERP results from the single-target detection task revealed no significant differences between groups for the mean amplitudes of the N2pc and P3 components, or peak latency of the P3.

ASD and comparison groups differed in their relationship between the behavioral results on the AB color-binding task and ERP measures on the single-target detection task. For the ASD group, but not the comparison group, the AB depth was positively correlated with P3 peak latency in both the left ($r = .732$; $p < .01$) and right ($r = .637$; $p < .05$) hemispheres.

Exploratory analyses examining the relationship between ASD diagnostic measures and ERP results revealed a negative correlation between ADOS Social Affect scores and the amplitudes of the N2pc ($r = -.728$, $p < .01$) and left-lateralized P3 components ($r = -.638$, $p < .05$). Both verbal and nonverbal scores on the ADI were negatively correlated with the mean amplitudes of the N2pc and left-lateralized P3 components.

Conclusions:

Though no differences were found between ASD and comparison groups in any measures of the AB or the ERP components, the relationship between the AB and ERP components differed between the groups. For individuals with ASD, but not comparison individuals, AB depth was positively correlated with the P3 latency, indicating that individuals who are slower to process a single target also show a larger AB to dual-targets. Finally, exploratory analyses suggest that the size of the N2pc and left-lateralized P3 components might be related to social cognition impairments in ASD.

17 **182.017** EEG Neural Variability Distinguishes 16p11.2 Deletion and Duplication Carriers

R. Al-Jawahiri*, M. Jones and E. Milne, The University of Sheffield, Sheffield, United Kingdom*

Background:
Copy number variations (CNV) at the 16p11.2 chromosomal locus (~600 kb breakpoints 4–5 (BP4-BP5)) are associated with myriad clinical features including intellectual disability, autism spectrum disorder (ASD), epilepsy, and language and motor delays. Importantly, trends of reciprocal phenotypic differences between deletions (DEL) and duplications (DUP) have been consistently observed across multiple traits (e.g., brain volume and structures (Chang et al., 2016; Maillard et al., 2014), BMI (Jacquemont et al., 2011), EEG signals (LeBlanc and Nelson, 2016; Jenkins et al., 2016), etc.), which have been interpreted as indicating gene-dosage effects. However, as 16p11.2 CNVs are rare, there has been only four studies (LeBlanc and Nelson, 2016; Jenkins et al., 2016; Berman et al., 2016; Hudac et al., 2015) that phenotyped the EEG activity of carriers and no study examined reciprocal neural variability patterns.

Objectives:

The aim of this study is to determine whether 16p11.2 DEL and DUP carriers demonstrate a distinct and reciprocal pattern of EEG activity as represented by neural variability and signal-to-noise (SNR) measures.

Methods:

EEG data of the 16p11.2 CNV and typical groups were previously collected as part of the Simons Variation in Individuals Project (Simons VIP Consortium, 2012). Neural variability measures, as estimated by single trial ERP and spectral power analyses in the alpha and beta frequency bands, in addition to SNRs, were analysed in the CNV (n=28) and typical groups (n=11).

Results:

Intra-participant variability in ERP amplitude and absolute alpha power was significantly higher in DEL compared to controls (and compared to DUP for the latter measure). Relative alpha variability was significantly lower in DUP relative to both DEL and controls. SNRs did not differ between the groups. Patterns of EEG activity did not support indications of gene-dosage effects.

Conclusions:

The findings indicate that 16p11.2 CNV groups have a distinctly atypical pattern of EEG activity, as indexed by neural variability measures, that is gene-dosage independent. The overall neural variability patterns were conceptualised as relating to cognitive processing and neural plasticity.

18 **182.018** EEG Phenotype in Angelman Syndrome Differs between Genotypes

J. F. Hipp[1], *L. M. Bird*[2], *P. Garces*[3], *M. Hoener*[4], *S. Jeste*[5], *O. Khwaja*[6], *M. L. Krishnan*[7], *M. Miller*[8], *H. Purtell*[9], *A. Rotenberg*[9], *W. H. Tan*[10] *and J. Frohlich*[11], *(1)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, Basel, Switzerland, (2)Department of Psychiatry, UCSD, San Diego, CA, (3)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development. Roche Innovation Center Basel, Hoffmann-La Roche, Basel, Switzerland, (4)Roche Innovation Center, Basel, Switzerland, (5)University of California, Los Angeles, Los Angeles, CA, (6)F. Hoffmann - La Roche AG, Basel, Switzerland, (7)Research and Early Development, Roche Innovation Center, Basel, Switzerland, (8)Roche Pharmaceutical Research and Early Development - NORD, Basel, Switzerland, (9)Neurology, Harvard Medical School, Boston, MA, (10)Genetics, Harvard Medical School, Boston, MA, (11)University of California Los Angeles, Los Angeles, CA*

Background:: Angelman syndrome (AS) is a neurodevelopmental disorder characterized by a specific set of clinical features including intellectual disability, movement disorders, limited speech, and epilepsy [Angelman et al., 1965], and confers increased risk for autism spectrum disorder. Loss of function of *UBE3A* is necessary and sufficient for AS. This paternally imprinted (i.e., silenced) gene encodes ubiquitin-protein ligase and is critical for normal neuronal development. There are several AS genotypes that present with different clinical severity [Moncla et al., 1999]: 1) deletions of 15q11.2-q13.1 on the maternal allele, which includes *UBE3A* and several other genes, most notably three non-imprinted gamma-aminobutyric acid (GABA)-A receptor subunit genes *GABRA5*, *GABRB3*, *GABRG3*, and 2) mutations that affect the maternal copy of *UBE3A* (e.g., loss of function *UBE3A* mutations, unipaternal disomy, and imprinting mutations). Biomarkers reflecting the disease pathophysiology are crucial for the development of pharmacological treatments of AS. Electroencephalography (EEG) is a promising candidate biomarker and functional readout of neuronal activity in AS, characterized by excessive delta oscillations [Sidorov et al, 2017]. However, it remains unknown if this EEG phenotype differs between genotypes. Such knowledge is important for both understanding AS pathophysiology and informing the design of possible future intervention studies.

Objectives: To examine EEG characteristics of AS patients by genotype and, specifically, to compare spontaneous EEG spectral power between 1) AS genotype groups and 2) AS patients and typical developing (TD) controls.

Methods: Clinical EEG recordings were obtained from a National Institutes of Health (NIH) natural history study of AS. A total of 66 datasets, including longitudinal data, were obtained from 43 unique subjects (13 non-deletion, 30 deletion) ranging in age from infancy to adulthood. Age-matched control data were recorded with the same EEG system from 51 TD children. Data were recorded in the awake state and preprocessed to remove physiological artifacts. Power spectral densities (PSDs, 1-32 Hz) were computed using a Morlet wavelet transform. PSDs where averaged across electrodes and across visits for subjects with multiple visits. A between-group analysis examined spectral power differences between AS subjects and controls; a within-group analysis examined spectral power differences between AS subjects with different genotypes. Statistical analysis compared log-transformed PSDs using t-test.

Results: Individuals with AS are characterized by excessive delta-band power compared to controls ($p < 0.05$, Bonferroni corrected across all frequencies; peak frequency 2.7 Hz). Deletion and non-deletion groups both show excess delta-band power — however, delta power is significantly greater in the deletion genotype ($p < 0.05$).

Conclusions: Differences in EEG delta power between deletion and non-deletion AS genotypes suggest a role in AS pathogenesis for non-imprinted 15q11.2-q13.1 genes or regulatory elements within this region. For instance, given the relevance of GABAergic signaling for electrophysiological oscillations, deletions of the genes *GABRA5, GABRB3, GABRG3* may contribute to greater delta power in some patients. These findings suggest differences in disease pathophysiology between AS patients with different genotypes, and, moreover, support the use of EEG as a stratification biomarker and functional readout in AS.

19 **182.019** EEG-Based Single Trial Classification Emotion Recognition: A Comparative Analysis in Individuals with and without Autism Spectrum Disorder

J. M. Mayor Torres[1,2], *E. J. Libsack*[1], *T. Clarkson*[1], *C. M. Keifer*[1], *G. Riccardi*[2] *and M. D. Lerner*[3], *(1)Stony Brook University, Stony Brook, NY, (2)Department of Information Engineering and Computer Science, University of Trento, Trento, Italy, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background: Recent studies support the use of novel statistical techniques, including EEG-based single trial classification, to better understand individual differences in neural responses to emotion reappraisal tasks (Singh & Singh, 2017) a core deficit in Autism Spectrum Disorder (ASD). The Late-Positive-Potential (LPP) is an event-related potential (ERP) that occurs 400-1500ms (Ferri et al., 2012) post-stimulus, is related to emotion reappraisal, and is attenuated in ASD (Benning et al., 2016). Research in typically developing (TD) populations (Mehmood, & Lee, 2016) has evaluated EEG-based single trial classification using LPP features to predict neural response to emotion categories. However, little is known about how well these pipelines can predict emotion states in individuals with and without ASD. Exploring the performance of a novel EEG single trial emotion classification pipeline in TD and ASD groups can advance understanding of both functional network-activation and of emotion reappraisal in individuals with ASD relative to TD peers.

Objectives: Evaluate the performance of a novel EEG single trial classification pipeline for predicting pleasant/unpleasant emotions elicited by DANVA-2 (Nowicki, 2004) stimuli in TD and ASD groups, as well as the capacity of models in one group to predict pleasant/unpleasant emotions in the other.

Methods: 17 participants (M=13.15, SD=1.36) including 9 TD and 8 ASD with ADOS-2 confirmed diagnosis (Lord et al., 2012). For each participant we ran a 3-fold cross-validation (Figure 1) including a complete dataset composed of 48 affective faces (examples) times the corresponding LPP time-points as features. We evaluated three LPP windows per-channel: early (400-800ms), middle (800-1200ms), and late (1200-1500ms). We then used the top channels modality (Kushaba, et al., 2011) to automatically select the two most predictively-sound channels per fold. Subsequently, we compared the predictive power of the top two predictively-sound channels in the TD model to the top two channels in the ASD model and vice versa to examine generalizability of these models across diagnostic groups (different group channel modality).

Results: The model, with high accuracy, predicted concurrent emotion in both TD and ASD groups using the identified top channels (Figure 2A). The average Precision (Pr) and Recall (Re) differed between modalities, and – crucially – between TD/ASD groups for the LPP middle window features (Figure 2B & 2C); These values differed between modalities across all three windows (all F(1,30) > 178, all p < .001). For instance, in the middle window the degradation in predictive Precision was 35.2% for TD and 34.2% for ASD between modalities (Figure 2C).

Conclusions: Our results suggest that LPP response represents an important set of features for pleasant/unpleasant face-elicited emotion prediction across/between TD/ASD groups. However, when the top channels for each group were used to predict the emotion state of the facial stimulus in the opposite group, the recall and precision metrics degraded significantly. Moreover, the cross-group model results lend support to the proposition that individuals with ASD demonstrate more diffuse functional neural-networks during emotional reappraisal than TD individuals, which is consistent with structural connectivity findings (Rudie et al., 2013).

182.020 Electrophysiological Biomarkers in Dup15q Syndrome: Evaluation of Clinical Predictors and Longitudinal Stability

V. Saravanapandian[1], *J. Frohlich*[1], *C. DiStefano*[1], *S. Huberty*[2] *and S. Jeste*[3], *(1)University of California Los Angeles, Los Angeles, CA, (2)Mcgill University, Montreal, QC, Canada, (3)University of California, Los Angeles, Los Angeles, CA*

Background:

Dup15q syndrome is a neurodevelopmental disorder characterized by global developmental delay, hypotonia, intellectual disability (Battaglia et al, 2010), and an increased risk for both autism spectrum disorder (ASD) and epilepsy (Conan et al, 2014). Our previous study identified a unique electrophysiological signature in the form of increased beta oscillations (12-30 Hz) that distinguish Dup15q children from typically developing and non-syndromic ASD children (Frohlich et al, 2016). This EEG signature strongly resembles the pattern induced by gamma-aminobutyric acid alpha subunit (GABAA) receptor modulation and likely reflects overexpression of the GABAA receptor genes in the syndrome. With rigorous data collection in a much larger cohort, we have now quantified beta oscillations longitudinally and examined its relationship to clinical variables, which will help evaluate its properties as a potential biomarker to be used in longitudinal and intervention studies.

Objectives:

To determine: 1) whether beta power relates to clinical and demographic features including age, duplication type, epilepsy, IQ, social, communication, adaptive and motor skills in individuals with Dup15q syndrome and 2) whether beta power is stable over time.

Methods:

Spontaneous resting state EEG was recorded from n=56 Dup15q syndrome patients (age range: 5 months - 41 years) seen both at UCLA and at the National Dup15q family conferences (IDDRC-NIH Grant#U54HD087101). Participants under medications that pharmacologically elicit beta oscillations were excluded. Relative beta power was computed, averaged across the whole scalp and simple linear regression models were implemented to model effects of clinical features. In participants who had follow-up EEG recordings (n=13, age range: 15-162 months), a generalized linear mixed model was used to model longitudinal beta power. Clinical measures tested included verbal and nonverbal cognition based on the Mullen Scales of Early Learning, adaptive function based on the Vineland Adaptive Behavior Scales (VABS), and autism severity based on the Autism Diagnostic Observation Schedule (ADOS).

Results:

Epilepsy diagnosis predicted beta power (R^2=0.1839 P=0.0011) in Dup15q syndrome, consistent with our previous findings. A trend towards younger participants having higher beta oscillations was seen but not statistically significant (R^2= 0.0658, P=0.0612). Verbal, nonverbal cognition and adaptive skills did not predict beta power. Autism severity was associated with increase in beta power but not statistically significant (R^2= 0.1703, P = 0.0632). Beta power was significantly stable over time (P = .003), except in three participants who developed epilepsy between visits and beta power reduced after seizure onset.

Conclusions:

Elevated beta oscillations in Dup15q syndrome appear to be stable over time in the absence of epilepsy. Further investigation is needed to evaluate EEG power changes after epilepsy onset, and to identify whether beta oscillations represent a protective biomarker for the development of seizures. The lack of a relationship with behavior reinforces the hypothesis that the unique brain activity pattern seen in Dup15q syndrome reflects the overexpression of the GABAA receptor genes and proves to be a robust biomarker of disease. Identification of brain-based biomarkers in rare disorders like Dup15q is instrumental in understanding the underlying biology of atypical brain development and can be used in targeted therapeutic trials.

182.021 Electrophysiological Markers of Resting-State Neural Network Abnormalities in Children with ASD, ADHD, and Co-Occurring ASD+ADHD

E. Shephard[1], *C. Tye*[2], *K. L. Ashwood*[3], *B. Azadi*[4], *M. H. Johnson*[5], *P. Asherson*[6], *G. McLoughlin*[7] *and P. Bolton*[2], *(1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom of Great Britain and Northern Ireland, (2)Department of Child & Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Child and Adolescent Psychiatry, King's College London, London, United Kingdom, (5)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (6)King's College London, London, United Kingdom, (7)King's College London, London, United Kingdom of Great Britain and Northern Ireland*

Background: Autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD) frequently co-occur but the reasons for this overlap are unclear. Abnormalities in oscillatory functional neural networks have been associated with ASD and ADHD, and may help to disentangle the neurobiological basis of these disorders and their co-occurrence. However, no previous work has compared oscillatory neural networks between ASD, ADHD, and co-occurring ASD and ADHD (ASD+ADHD).
Objectives: The objective of this study was to identify similarities and differences in resting-state oscillatory functional neural networks in children with ASD, ADHD, co-occurring ASD+ADHD, and typically developing control children.

Methods: Resting-state electrophysiological recordings were collected from boys with ASD (*n* = 19), ADHD (*n* = 18), ASD+ADHD (*n* = 29), and typical development (TD, *n* = 26). Oscillatory neural networks in delta (1-3Hz), theta (4-8Hz), alpha (8-12Hz), and beta (12-20Hz) frequencies were compared between groups using graph theoretical methods.

Results: Children with ASD showed a hypoconnected theta network and reduced local theta network inter-connectedness compared to children with ADHD, and ASD symptoms predicted greater hypoconnectivity in theta and beta networks. In contrast, children with ADHD showed widespread hyperconnectivity in theta and beta frequencies compared to TD and ASD children and limited theta fronto-posterior hypoconnectivity compared to TD. ADHD symptoms predicted greater hyperconnectivity. Children with ASD+ADHD showed theta network hyperconnectivity compared to TD and beta network hypoconnectivity compared to TD and ADHD children.

Conclusions: Children with ASD and ADHD were dissociable based on abnormalities in resting-state oscillatory networks, while children with ASD+ADHD showed evidence of both ASD-related hypoconnectivity and ADHD-related hyperconnectivity. These findings suggest ASD and ADHD are associated with distinct neurobiological atypicalities, which manifest together in co-occurring ASD+ADHD.

22 **182.022** Event-Related Potentials Linked to Executive Function Reflect Individual and Developmental Differences in Children with Autism Spectrum Disorders

R. Gilbert[1]*, L. J. Nelson*[2] *and S. Faja*[1]*, (1)Boston Children's Hospital, Boston, MA, (2)Boston University, Boston, MA*

Background: Many children with autism spectrum disorder (ASD) have difficulty with executive function (EF), which involves complex problem solving and goal-directed behavior, in comparison to typically developing children. The N2 event-related potential (ERP) component is generally associated with EF, and may specifically reflect the neural correlates of inhibition and conflict monitoring (Faja et al., 2016). Previous research has shown differences in the scalp distribution of the N2 component, with more widespread posterior and left-lateralized activation for younger children and children with reduced EF (e.g., Lamm et al., 2006). Examining age-related differences in the neural underpinnings of the N2 component in children with ASD may offer insight into the nature of EF challenges in ASD (difference versus delay) and enable interpretation of individual differences relative to age expectations.
Objectives: To explore individual differences and development of EF by examining age-related changes in behavioral performance and N2 responses, particularly their scalp distribution, during a Go/NoGo task.

Methods: Participants included 67 children diagnosed with ASD aged 7 to 11 grouped by age (40 children ages 7-9.49 and 27 children ages 9.5-11 years). EEG was collected while participants completed a cued Go/NoGo task. Neural responses were recorded and N2 mean amplitude and latency was characterized for the go and nogo conditions at Fz and Cz. Twenty-one younger and 16 older children provided usable ERP data. Accuracy was also collected during the task for all participants.

Results: Repeated-measures ANOVA (condition x electrode site x age group) with peak amplitude suggested that the N2 component becomes more focused around Fz with age. Older children with ASD exhibited stronger activation at Fz relative to Cz, in comparison to younger children with ASD, who showed strong activation at Fz and moderate activation at Cz (electrode x age: F(1,35)=4.31, p=0.045). Behaviorally, accuracy was higher for the go than nogo condition (F(1,65)=123.93, p≤0.001). Older children were more accurate during both the go and nogo conditions, as compared to younger children (F(1,65)=13.62, p≤0.001) However, the interaction between age group and go/nogo condition was not significant (F(1,65)=1.79, p=0.186). Better performance across go/nogo conditions related to smaller peak amplitude (greater efficiency) in the older cohort at Fz, r(16)=0.505, p=0.046, but was not significant in the younger cohort.

Conclusions: Individual and developmental differences in scalp activation of the N2 component appear related to neural activation during an EF task. Increased specificity of N2 peak amplitude at Fz with age compared to Cz may indicate greater anterior shift in the neural source of the N2 or a decreased posterior contribution as EF develops in school age children with ASD. Additionally, the relation between greater neural efficiency at Fz and improved behavioral performance across conditions in the older cohort suggests individual differences in EF ability beyond the effects of age can be observed at the neural level.

23 **182.023** Evidence of Altered Neural Responses to Hearing the Own Name in Autism Spectrum Disorder

R. El Kaddouri[1]*, A. D. Nijhof*[2]*, J. Goris*[3]*, M. Brass*[3] *and J. R. Wiersema*[4]*, (1)Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)Institute of Psychiatry, King's College London, London, United Kingdom, (3)Department of Experimental Psychology, Ghent University, Ghent, Belgium, (4)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: Diminished responding to hearing the own name in infancy is one of the earliest and strongest predictors of later diagnosis of ASD. Remarkably, as of yet there is no study that systematically investigated the neural correlates of hearing the own name in individuals who received a diagnosis of ASD.
Objectives: Our aim was to study the neural responses, by means of event-related potentials (ERPs), to hearing the own name in children and adults with a formal diagnosis of ASD. Atypical processing of the own name in ASD in childhood and adulthood would suggest that this is related to a fundamental deficit. It may also point to specific mechanisms underlying the lack of response to the own name in children at risk for ASD. Based on earlier research in neurotypicals, we expected stronger positive parietal activity when hearing the own name versus other (familiar and unfamiliar) names in neurotypicals, and this effect to be diminished or absent in individuals with ASD.

Methods: The study on adults is finalized, while the study on children is still ongoing. 24 adults with ASD and 24 neurotypical adults participated in the experiment. Data of 12 children with and without ASD were analyzed. Participants carried out an auditory oddball paradigm. The sequence of stimuli comprised one frequently presented standard sound (66%), an infrequent target sound (4%), and three categories of names that were presented as equally infrequent task-irrelevant deviants: participants' own name (10%), the name of a close other (10%), and the name of another person unknown to them (10%). They were instructed to only respond with a button press to the target sound.

Results: A late parietal positivity (PP) was observed specifically for own names in neurotypical adults, indicating enhanced attention to the own name. This preferential effect was completely absent in adults with ASD. Source localization analyses associated this group difference to diminished activation in the right temporo-parietal junction (rTPJ) in adults with ASD. ASD diagnosis could be predicted with fair accuracy, based on own name related brain activity. Data collection is still ongoing in children but early analyses show very similar patterns as seen in adults with ASD. Also children with ASD significantly differ from their typically developing peers, in that they do not show amplification of parietal positive activity, which was observed in neurotypical children. Both the adult findings and results from the analyses on the full sample of children will be presented during the meeting.

Conclusions: The findings indicate atypical neural responses to hearing the own name in individuals with ASD, both in children and adults. In adults, this was associated with decreased rTPJ activation, a region that plays a key role in self-other distinction and mentalizing and has been strongly implicated in ASD in earlier research. Further research is warranted to evaluate the EEG response to the own name as a putative neurocognitive biomarker of ASD across the lifespan.

24 **182.024** Examining the Effect of Attention on Sensory Registration in Autism Spectrum Disorders

J. Crasta[1], *P. L. Davies*[2] *and W. J. Gavin*[3], *(1)Physical Medicine and Rehabilitation, Kennedy Krieger Institute, Baltimore, MD, (2)Colorado State University, Fort Collins, CO, (3)Human Development & Family Studies, Colorado State University, Fort Collins, CO*

Background: Individuals with autism spectrum disorders (ASD) have significant deficits in sensory processing and attention. Researchers have suggested that sensory processing deficits in ASD may be associated with deficits in attention. However, there is a lack of research systematically examining the impact of attention on sensory processing at the neural level.

Objectives: The study examined the effect of attention on phases of neural auditory processing in individuals with autism spectrum disorders (ASD) using electroencephalography (EEG). We hypothesized that consciously directing attention to incoming information would result in more typical neural processing in individuals with ASD.

Methods: Participants included 24 young adults with high-functioning ASD (17 – 30 years; $M = 23.31$, $SD = 3.77$; 17 males) and 24 age-matched neurotypical individuals. All participants were administered a performance-based measure of attention, the Test of Everyday Attention, and filled out the self-report Adolescent/Adult Sensory Profile. Individuals with ASD had significantly greater attention deficits and sensory processing challenges compared to the neurotypical group. EEG data were recorded while they heard random presentations of four auditory stimuli (50 milliseconds in duration) at two different frequencies (1 and 3 kHz) and at two different intensities (50 and 70 dB). All participants completed two attention conditions; the passive condition involved only listening to the stimuli, followed by the active condition, wherein participants were instructed to press a button only to the 1 kHz 50 dB tone. For each condition, participants heard 80 trials of each tone in pseudo-random order with a two-second inter-stimulus interval. Repeated-measures ANOVAs were used to examine the N1-P2-N2-P3 amplitude and latency differences. Additionally, time-frequency analyses were used to examine neural oscillatory activity.

Results: Directing attention to the tones resulted in P2, N2, and P3 amplitude and latency differences for all participants. There were no group differences in N1, P2, N2, or P3 amplitudes for either attention condition. However, individuals with ASD had significantly longer N1, N2, and P3 latencies, suggesting delayed processing. N1 latency delays were present during both attention conditions. N2 and P3 latency delays were present during the passive condition but not during the active condition, implying an attention-based amelioration of the processing delay in ASD. Behavioral measures of sensory processing and attention correlated with neural measures of auditory processing, such that more efficient neural processing (shorter N1 latency) was associated with more typical attention and sensory processing abilities.

Conclusions: Actively directing attention to the tones impacts auditory processing, and may result in more typical processing in ASD. Study findings have significant implications related to understanding neural auditory processing in ASD and provide support that sensory processing issues in ASD are related to attention. Additionally, these results can help practitioners understand the neural basis of behavioral manifestations of ASD, especially those atypical behaviors that occur in response to sensory experiences in everyday activities.

25 **182.025** Exploring Mismatch Negativity Processing in Autism Spectrum Disorder during an Auditory Odd-Ball Task: Evidence from the EU-AIMS LEAP Cohort.

J. Ahmad[1], *P. Garces*[2], *D. V. Crawley*[1], *C. L. Ellis*[3], *E. Kong*[1], *E. J. Jones*[4], *J. Cooke*[1], *A. San Jose Caceres*[1], *J. Tillmann*[5], *T. Charman*[6], *J. K. Buitelaar*[7], *B. Oranje*[8], *D. G. Murphy*[9,10], *G. Dumas*[11], *L. Mason*[4] *and E. Loth*[1,12], *(1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development. Background:

The mismatch negativity (MMN) is an ERP component thought to index neural prediction, calculated by subtracting the *average* response to a standard repeating tone from a rarer deviant. Prior attempts at examining the MMN in ASD have been inconsistent, indicating either smaller, larger, earlier, later, or no group differences in MMN components. Critically, sample sizes have been small (approximately 10-35 per group), and the clinical profile of participants has varied. These inconsistencies may be due to methodological differences (including lack of power) and/or the existence of different ASD subgroups – given the recognition of the clinical and etiological heterogeneity of ASD. Recent investigations of MMN have been framed within the predictive coding hypothesis, which suggests that the brain matches incoming stimuli against expectation. According to this account, participants with ASD should show a smaller MMN, since increased sensory drive may lead to standard tones being processed more similarly to deviants.

Objectives:

1. In a large heterogeneous sample (N= 519) we aim to test differences in the MMN between the ASD and control groups overall, and split age groups (adults, adolescents, children),
2. To identify potential subgroups of ASD with MMN abnormalities using normative modeling.
3. To correlate MMN markers with ASD symptomatology (social interactions, repetitive behaviours, and sensory processing).

Methods:

The project included participants from the EU-AIMS LEAP study. Participants passively listened to an auditory oddball stream, consisting of standards (1000Hz, 50ms), and 3 deviant types, each with a probability of 6% (duration (1000Hz, 100ms), frequency (1500Hz, 50ms), and combined frequency + duration deviants (1500Hz and 100ms)). The MMN was analysed at Fz. After extensive quality control and preprocessing, N=257 individuals with ASD/ASD-ID, and N=193 individuals with TD/ID were retained for analysis (6-30; IQ 50-148). Case control differences, and normative modelling with Gaussian Processes were conducted to quantify ASD participant's deviation from the age relevant TD model mean.

Results:

Contrary to expectations, ASD participants scored similarly to controls in respects to each MMN types [for amplitude and peak latency all *F*s<.58, *p*s>.27]. When analyses were split by age groups (adults, adolescents, and children) or by testing site, all comparisons remained non-significant [MMN components: *p*s>0.07]. The MMN amplitude and latency did not correlate with ASD symptomatology [*r*s<.08, *p*s>.65], but the MMN peak correlated with age: younger participants had a larger MMN [*p*= 9.5192E^{-8}, *r*=.25]. Normative modelling revealed the percentage of ASD participants with values within +- 1 SD of the TD mean (71.20%), less than 1-2SD (9.72%), less than 2SD (3.50%), greater than 1-2SD (13.61%), and more than 2SD (1.95%).

Conclusions:

To our awareness, this is the largest study of an oddball task in ASD. We found no evidence for abnormalities in ASD on the MMN –this was consistent when moderating variables (e.g. age, or inter-site variability) were considered. Future analysis will investigate differences in higher-level predictions, more sensitive measures of onset latency, and a scalp-wide effects. Furthermore, oscillatory time-frequency analysis will be conducted.

26 **182.026** Functional Connectivity Alterations of the Prefrontal Thalamic Pathway in Autism Spectrum Disorder Are Age and Sex Dependent

A. Rausch[1], *M. H. P. Reinartz*[1], *C. B. Beckmann*[1,2,3], *J. K. Buitelaar*[1,4], *W. B. Groen*[5] *and K. V. Haak*[1,3], *(1)Radboud University Medical Center Nijmegen, Donders Institute for Brain, Cognition and Behaviour, Department of Cognitive Neuroscience, Nijmegen, Netherlands, (2)Centre for Functional MRI of the Brain (FMRIB), University of Oxford, Oxford, United Kingdom, (3)Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, Netherlands, (4)Karakter Child and Adolescent Psychiatry University Centre, Nijmegen, Netherlands, (5)Karakter Child and Adolescent Psychiatry University Center, Nijmegen, Nijmegen, Netherlands*

Background:

The thalamus maintains connections throughout the brain and its dysfunction has been associated with autism. However, DTI studies investigating structural functional connectivity are inconsistent and little is known about subregion-level thalamic functional connectivity (FC) in ASD. Therefore, we investigated subregion thalamo-cortical FC strength in ASD using a discovery sample and four replication samples of the ABIDE I dataset. The replication samples varied from our discovery sample with respect to sample size, scanning site and imaging parameters, sex-ratio, and the age range studied.

Objectives:

To delineate robust thalamic subregion abnormalities in ASD, we aimed to reproduce our findings from an adolescent discovery sample across four distinct replication samples.

Methods:

In the discovery sample (ASD=19 male/1 female, 12-22y; CTR=22male/3female, 13-22y), using an age and gender corrected correlation analysis, we calculated the full-correlations between four thalamic subregions (prefrontal (PF-T), temporal (TE-T), parietal-occipital (OP-T) and sensory, primary motor and pre-motor (SM-T)) and their associated cortical lobes separately in resting-state fMRI scan data. We identified increased FC strength along the right prefrontal thalamic nucleus (PF-T) and the right ventromedial prefrontal cortex (vmPFC). In the planned analysis in the four replication samples ($ASD_{Leuven29}$=14 male, 18-32y; $CTR_{Leuven29}$=15 male, 18-29y; $ASD_{Leuven35}$=12 male/3 female, 12-16y; $CTR_{Leuven35}$=15 male/5 female, 12-16y; ASD_{USM101}=58 male, 11-50y;CTR_{USM101}=43male, 8-39y; ASD_{NYU184}=68 male/11 female,7-39y; CTR_{NYU184}=79 male/26 female, 6-31y) we extracted the mean time series between the right PF-T and vmPFC ($PF\text{-}T_{vmPFC}$ FC strength) and its r-to-*Z* transformed correlations were calculated. Using *lmrob* a robust linear modelling method as implemented in the statistical R software package 'robustbase', we predicted the effect of age, sex and symptom severity (SRS) or diagnostic group status (Group) on $PF\text{-}T_{vmPFC}$ FC strength.

Results:

The $PF\text{-}T_{vmPFC}$ FC strength effect was dependent on site when investigating the SRS score (χ^2(*df*=1)=8.17, df=3, p=0.043) across all sites, or absent when investigating diagnostic group across all sites. However, we found sex dependent effects in both of the samples that contained females (Leuven35=(χ^2(*df*=1)=28.10, df=1, p<0.0001; NYU184=(χ^2(*df*=1)=4.33, df=3, p=0.037)) when investigating the SRS score, but only in one sample using diagnostic status as predictor (Leuven35=(χ^2(*df*=1)= 12.5, p<0.0001)). In one sample, we found interaction effects with diagnostic group and age (Leuven29= χ^2(*df*=1)=6.06, p<0.015)). In 2 of the 4 samples, there was an effect of age ((Leuven29= χ^2(*df*=1)=5.96, p<0.015; USM101= χ^2(*df*=1)=4.17, p<0.05). In the sample that was the most similar to the discovery sample, Leuven35, we found that sex, age and diagnostic status as well as sex, age and SRS symptom scores were robust predictors of right $PF\text{-}T_{vmPFC}$ FC strength (all p-values <0.001).

Conclusions:

Increased thalamic FC strength in ASD was identified in prefrontal nucleus within our discovery sample. PF-T_{vmPFC} FC strength was not predicted by SRS scores or diagnostic status across all sites per se, while there were age and sex interaction effects with diagnostic group. These findings suggest that there are age and sex specific developmental thalamic-cortical pathways in the etiology of ASD.

27 **182.027** Imaging-Genetics of Gender Differences in ASD: Sex-Specific Additive Effects of Oxytocin Receptor Gene Polymorphisms on Reward Circuitry

L. M. Hernandez[1]*, K. E. Lawrence*[1]*, S. A. Green*[2]*, N. T. Padgaonkar*[1]*, D. Geschwind*[1]*, S. Y. Bookheimer*[2] *and M. Dapretto*[2]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA*

Background: Sex differences in the prevalence of Autism Spectrum Disorder (ASD) are well documented; yet, the mechanisms underlying this gender bias remains unknown. As the ASD phenotype is defined primarily by social impairments, exploring sex differences in brain networks and genes associated with social behavior is a logical first step. Allelic variations on the oxytocin receptor gene (*OXTR*) have been associated with increased rates of ASD (LoParo 2014), and animal models suggest OXTR signaling in the nucleus accumbens (NAcc) is crucial for typical social behavior (Keebaugh 2015). In a predominantly male sample, we recently showed that *OXTR* risk-allele-dosage was associated with decreased NAcc-reward circuit connectivity in ASD youth, whereas typically developing (TD) carriers of disease-associated variants showed increased NAcc-frontal connectivity, suggesting a compensatory mechanism in the face of increased genetic risk (Hernandez 2017). Importantly, however, evidence from animal models indicates gender-specific expression of the *OXTR* in the brain (Olazábal 2016) and gender-specific associations between *OXTR* methylation and brain volume have been documented in humans with psychiatric disorders (Rubin 2016).
Objectives: To examine the moderating effects of gender on the relationship between *OXTR* risk-allele-dosage and functional connectivity of the brain's reward network in males and females with ASD (ASD-M, ASD-F) and matched TD controls (TD-M, TD-F).

Methods: DNA was genotyped for four ASD-associated *OXTR* SNPs (rs53576/rs237887/rs2254298/rs1042778). Participants were 32 ASD-F, 37 ASD-M, 33 TD-F, and 34 TD-M, ages 9-17 (males were the same subjects as in Hernandez 2017). Children completed a resting-state fMRI scan. ASD-F/TD-F data were processed according to the pipeline used for ASD-M/TD-M in Hernandez 2017. Data were motion scrubbed, activity was extracted from bilateral-NAcc and correlated with all other brain voxels to create resting-state maps. Single-subject resting-state maps were combined and compared at the group level, modeling the number of *OXTR* risk alleles as a covariate of interest. Results were thresholded at $z>3.1$ ($p<.001$), corrected for multiple comparisons at $p<.05$.

Results: Greater *OXTR*-risk-allele-dosage was associated with greater connectivity between NAcc and ventro-medial prefrontal cortex in TD-F, and greater connectivity between NAcc and subcortical brain regions in ASD-F. Comparing ASD-F to ASD-M, a significant interaction was detected such that as risk-allele-dosage increased, ASD-F showed an increase in connectivity between the NAcc and frontal and subcortical brain regions whereas ASD-M showed a decrease in connectivity with these same brain regions. Further, in ASD-F greater NAcc-frontal connectivity was associated with better social cognition measured by the Social Responsiveness Scale ($p=.001$); mirroring the brain-behavior relationship we previously reported in TD-M (Hernandez 2017).

Conclusions: In the face of increased genetic risk on the *OXTR,* unlike ASD-M, ASD-F showed increased NAcc-frontal connectivity, the same pattern observed in TD-M. Importantly, this increase in NAcc-frontal connectivity was associated with better social cognition in both ASD-F and TD-M groups. This neurobiological compensatory mechanism supports a female protective model whereby a greater number of genetic/environmental risk-factors are required for ASD-F to display altered brain connectivity and to exhibit high levels of ASD-associated symptomatology, which may ultimately help to explain observed sex differences in the prevalence of ASD.

28 **182.028** Impact of Gender on Resting-State Network Connectivity in Youth with ASD

K. E. Lawrence[1]*, L. M. Hernandez*[1]*, S. A. Green*[2]*, N. T. Padgaonkar*[1]*, H. Bowman*[3]*, S. Y. Bookheimer*[2] *and M. Dapretto*[2]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (3)CART, UCLA, Los Angeles, CA*

Background: Autism spectrum disorder (ASD) is consistently shown to have a higher prevalence rate in males than females (Fombonne, 2009), and nearly all neuroimaging studies in ASD to date have used samples that are predominantly or entirely male (Philip et al., 2012). Such neuroimaging studies in males have found differences in resting-state functional connectivity between participants with ASD and typically developing (TD) controls, with multiple studies particularly implicating the salience network in ASD (Uddin et al., 2015). However, genetic and behavioral evidence suggests that findings from males with ASD may not generalize to their female counterparts, as females require a greater genetic load to develop ASD (Werling & Geschwind, 2013) and may display differences in symptom profiles relative to males with ASD (Lai et al., 2015). Furthermore, a couple of recent neuroimaging studies have reported some gender differences in brain connectivity among individuals with ASD (Alaerts et al., 2016; Ypma et al., 2016), underscoring the importance of further investigations into the impact of gender on functional connectivity in ASD.
Objectives: Examine how functional connectivity findings within the salience network differ between girls and boys with ASD, as well as how girls and boys with ASD differ from gender-matched TD controls.

Methods: As part of an NIH-funded multi-site network, resting-state functional magnetic resonance imaging (fMRI) data was collected from a total of 195 individuals with ASD and TD controls. An approximately equal number of girls and boys contributed data to each group, and all subjects were between the ages of 8 and 17 years old. Salience network connectivity was examined using a seed located in the anterior insula (Seeley et al., 2007), with nuisance regressors and ICA-AROMA used to reduce potential motion confounds (Pruim et al., 2015). Site, IQ, and pubertal development were included as covariates at the group level. Comparisons between the female and male subjects of the ASD and TD groups were completed in FSL and prethreshold masked to focus on those areas which displayed significant positive or negative connectivity with the SN seed. Connectivity z-scores from significant group clusters were subsequently extracted and correlated with behavioral measures.

Results: Relative to boys with ASD, girls with ASD displayed greater positive connectivity with premotor regions and reduced positive connectivity with insular and frontal areas. Girls with ASD furthermore demonstrated increased negative connectivity with sensorimotor regions compared to boys with ASD, who instead had greater negative connectivity with temporal and cerebellar structures. When comparing girls and boys with ASD to their TD counterparts, there were no significant differences between girls with and without ASD. However, relative to TD boys, boys with ASD displayed significant reductions in both positive and negative connectivity with temporal and parietal regions.

Conclusions: These findings suggest that brain regions associated with salience detection and sensorimotor processing are differentially connected in males and females with ASD. Furthermore, our results demonstrate that brain alterations found in males with ASD may not generalize to females with ASD and emphasize the necessity of considering gender when investigating brain-based phenotypes in ASD.

182.029 Increased Spontaneous Blink Rate Suggests Dopaminergic Function Abnormalities in Individuals with Fragile X Syndrome:

N. Woodruff[1], *S. P. White*[2], *M. W. Mosconi*[3], *J. Wang*[4], *E. Pedapati*[5], *C. A. Erickson*[5], *M. J. Byerly*[6], *J. A. Sweeney*[7] *and L. E. Ethridge*[8], *(1)The University of Oklahoma, Norman, OK, (2)Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, TX, (3)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (4)Department of Psychology, Zhejiang University of Technology, Hangzhou, China, (5)Division of Child and Adolescent Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (6)Center for Mental Health Research and Recovery, Montana State University, Bozeman, MT, (7)Psychiatry, University of Cincinnati, Cincinnati, OH, (8)Pediatrics, University of Oklahoma Health Science Center, Norman, OK*

Background: Spontaneous blink rate (SBR) stands as a non-invasive measure of central dopaminergic function that has been studied in the context of a variety of neurological disorders; increased SBR is associated with increased dopaminergic activity and has been found in schizophrenia, and anxiety disorders. The relative ease of carrying out these studies offers a promising, cost-effective method to evaluate a possible role of dopaminergic dysfunction and anxiety in Autism Spectrum Disorders or related neuropathologies such as Fragile X Syndrome (FXS).

Objectives: To verify that a difference exists between spontaneous blink rates in FXS individuals relative to neurotypical controls, and identify any correlations between SBR and aberrant behavioral or electrophysiological measures associated with FXS, which would suggest a possible role of hyper- or hypo-dopaminergic states in specific FXS-related deficits.

Methods: EEG data was collected on 13 FXS patients and 12 matched controls (ages 14-56) while conducting a passive auditory habituation task consisting of 150 stimulus trains of four tones presented 500ms apart with an inter-train interval of 4000 ms. Virtual EOG channels produced from recorded EEG data, along with the EEG spatial topographies were used to identify blinks. Blinks were manually identified by evaluating EOG waveforms and verifying the topographical distribution of EEG activity at the peak waveform amplitude.

Results: Preliminary results indicate that FXS has a higher overall blink rate (mean = 0.58 blinks/sec, Mann-whitney U test p=0.03) compared to controls (mean = 0.32 blinks/sec). Blink rate during stimulus train presentation did not differ from overall blink rate for either group. In neurotypical controls, induced gamma EEG activity was negatively associated with SBR (r= -0.580 , p= 0.048), consistent with studies reporting DRD4-modulated gamma inhibition in fast-spiking interneuron/excitatory pyramidal cell networks in auditory cortex. While FXS exhibited overall higher induced gamma activity, F(1,27)=10.1, p=.004, they did not show a relationship between gamma and SBR, suggesting a breakdown in dopaminergic regulation of network inhibition.

Conclusions: Spontaneous blink rate may offer a simple, non-invasive measure of dopaminergic function that can be taken during passive tasks making this approach valuable to research involving very young, or intellectually disabled individuals. FXS showed increased SBR throughout the task but did not show a further enhancement of blink rate during stimulus presentation, indicating no enhanced startle response to the auditory stimuli. The combined results provide evidence for dopaminergic dysfunction which may be related to EEG phenotypes and potentially anxiety phenotypes in FXS but may only indirectly relate to sensory hypersensitivity associated with FXS. SBR combined with EEG easily translates to mouse models of FXS, suggesting a potentially powerful mechanism for exploring receptor-level dopamine dysfunction in FXS and its associated behaviors.

182.030 Individual Face Discrimination and the Influence of Fixation in ASD Measured with Fpvs EEG

S. Vettori[1], *S. Van der Donck*[2], *M. Dzhelyova*[3], *J. Steyaert*[4], *B. Rossion*[3] *and B. Boets*[4], *(1)K U Leuven, Leuven, Belgium, (2)KU Leuven, 3000 Leuven, Belgium, (3)Psychological Sciences Research Institute and Institute of Neuroscience, UCL, Louvain-la-Neuve, Belgium, (4)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium*

Background:

Fluently recognizing faces and facial expressions is highly important for our social interactions. Impaired and atypical face processing have often been postulated as a key deficit in autism spectrum disorders (ASD). Furthermore, decreased visual attention to the eye region has been suggested in ASD, as well as an increased preference for the mouth region of faces. Despite the great amount of research on face identity and facial expression recognition in ASD, results are mixed.

Objectives:

Therefore, we wish to examine face processing in ASD by means of an implicit and innovative EEG approach, and we will relate EEG findings to visual face scanning patterns assessed with eye-tracking.

Methods:

We combine fast periodic visual stimulation (FPVS) with scalp electroencephalography (EEG) and eye-tracking. The core idea of FPVS is that the periodicity of the electrophysiological response on the human scalp corresponds exactly with the periodicity (frequency) of the visual stimulation. Hence, it can be used for efficiently measuring categorization responses of complex visual stimuli in the human brain.

First, the ability to rapidly discriminate individual faces was assessed in matched groups of boys with (N = 23) and without (N=23) ASD. If oddball images of various facial identities are periodically interleaved in a series of identical faces, the sensitivity to facial identity can be quantified by assessing the neural response at this oddball frequency. Additionally, we manipulated the orientation of the faces (upright versus inverted), as well as the position of the fixation cross (the eye region versus the mouth region).

In a second paradigm, administered in the same groups, we examined spontaneous visual face processing both with frequency-tagging EEG (preferential neural processing) and with eye-tracking (preferential looking) . In this paradigm, the eye and the mouth region of a face are each flickering at a particular frequency, which allows to disentangle the neural processing of the eye versus mouth region. The neural responses to each of the face parts were quantified and were related to the simultaneous eye-tracking data.

Results: We observed a significantly lower neural sensitivity for individual face discrimination in the ASD group, as indicated by lower bilateral occipito-temporal responses. This group difference was present no matter whether the fixation was on the eye region or on the mouth region, but is specific for upright and not for inverted faces. At the conference we will also add and discuss the results of the second paradigm, investigating preferential neural processing and preferential looking of the eye region versus the mouth region of faces.

Conclusions:

The literature suggests that individuals with ASD show face processing impairments and atypical visual scanning patterns. We examined these hypotheses with an innovative EEG paradigm. We found impaired holistic processing of faces in the ASD group, not modulated by the position of the fixation cross. Additionally, we examined how spontaneous visual face processing patterns differ in children with ASD versus typically developing children, by measuring both which face part (eye or mouth region) is preferentially processed (EEG) and which part is preferentially looked at (eye-tracking).

31 **182.031** Interhemispheric Resting-State Functional Connectivity and Corpus Callosum Volume Changes in Autism

***S. Yao**, Q. Li, Z. Zhao, B. Becker and K. M. Kendrick, Life Science and Technology, UESTC, Chengdu, China*

Background: Autism spectrum disorder (ASD) has been associated with a number of potential structural and functional brain biomarkers using both region of interest and brain-wide approaches. A number of previous studies have suggested that reductions in functional interhemispheric connectivity and corpus callosum volume, may be associated with ASD[1], although this remains to be fully established in large datasets.

Objectives: We investigated whether resting-state interhemispheric functional connectivity and corpus callosum volumes were altered in ASD compared to healthy control subjects and if they were associated with symptom severity.

Methods: The present study used resting state fMRI and T1-weighted MRI data from 402 subjects with autism spectrum disorder (ASD) and 496 controls from the ABIDE database (http://fcon_1000.projects.nitrc.org/indi/abide). Interhemispheric resting state functional connectivity was computed using the 'voxel-mirrored homotopic connectivity' function implemented in the DPARSF software. We also conducted a structural region of interest (ROI) analysis on white matter segments using the corpus callosum mask from the Talairach Daemon database atlases. Group differences of the interhemispheric functional connectivity and the corpus callosum size were examined using a two-sample t-test, and a threshold of $p < 0.05$ false discovery rate (FDR) corrected at peak level was set for multiple comparisons. Associations with symptom severity in the ASD group (using ADOS scores) were also calculated by Pearson correlation.

Results: Two-sample t-tests on interhemispheric functional connectivity revealed decreased interhemispheric connectivity in the default mode network (dorsal medial prefrontal cortex (mPFC), ventral mPFC and posterior cingulate cortex (PCC)) the salience network (posterior insula (PI)), the mirror neuron system including inferior parietal lobule, precentral gyrus and superior temporal gyrus, thalamus and visual processing regions (lingual, fusiform and inferior occipital gyri) in ASD relative to control groups ($P_{FDR} < 0.05$). The PCC interhemispheric functional connectivity was negatively correlated the total ADOS scores (all 3 subscales - $r = -0.189$, $p = 0.004$) and both the communication ($r = -0.220$, $p = 0.001$) and social sub-scales ($r = -0.133$, $p = 0.044$). The PI interhemispheric connectivity was also negatively correlated with the ADOS communication sub-scale ($r = -0.147$, $p = 0.026$). The white matter ROI analysis of the corpus callosum showed significantly reduced volumes in both the anterior and posterior parts of the corpus callosum in the ASD compared to the control groups ($P_{FDR} < 0.05$), but these were not associated with ADOS scores. Results remained significant after including total brain volume and either full or verbal IQ measures as covariates.

Conclusions: Our findings provide evidence for both reduced resting-state interhemispheric functional connectivity and corpus callosum volumes in ASD subjects. Changes in posterior cingulate and insula interhemispheric functional connectivity are also associated with symptom severity and may represent useful potential ASD biomarkers.

32 **182.032** Is Implicit Processing of Fearful Faces Impaired in ASD?

***S. Van der Donck**[1,2], S. Vettori[1,2], M. Dzhelyova[3], J. Steyaert[4,5], B. Rossion[3] and B. Boets[1,4], (1)Center for Developmental Psychiatry, Katholieke Universiteit Leuven, Leuven, Belgium, (2)Leuven Autism Research Consortium (LAuRes), Katholieke Universiteit Leuven, Leuven, Belgium, (3)Psychological Sciences Research Institute and Institute of Neuroscience, UCL, Louvain-la-Neuve, Belgium, (4)Center for Developmental Psychiatry, KU Leuven, Leuven, Belgium, (5)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium*

Background: Being able to quickly read faces and facial expressions is crucial for social interactions, and even survival. Many studies suggest that individuals with autism spectrum disorder (ASD) show deficits in emotion recognition, especially with regard to fearful faces. In addition, it has been suggested that individuals with ASD may show a reduced preference for the eye region and may focus more on the mouth region.

Objectives: The present study aims at examining the nature of face processing impairments in 23 8-to-12 year old children with ASD versus 23 matched typically developing (TD) control children. In particular, we investigated the neural sensitivity to implicitly discriminate between neutral and fearful faces, and whether this relates to behavioural indices of facial emotional processing and to atypical visual scanning patterns of the face.

Methods: We combined fast periodic visual stimulation (FPVS) with scalp electroencephalography (EEG) and eye-tracking. The general principle of FPVS EEG is that it elicits a steady-state visual evoked potential at exactly the same frequency of visual stimulation. If oddball fearful faces are periodically interleaved in a series of neutral faces, sensitivity to these socio-communicative cues can be quantified by assessing the neural response at the oddball frequency. Additional within-subject manipulations comprised the orientation of the faces (upright versus inverted) and the positioning of the fixation cross (on the eye region versus on the mouth region). Behavioural indices of face processing comprised the detection of non-periodic emotional faces in a stream of neutral faces, the assessment of the Emotion Recognition Task and the Emotion-Matching Task, and the assessment of visual scanning patterns during explicit emotion recognition tasks.

Results: Neural responses at the oddball frequency and its harmonics are present in both groups of children, and both groups show a similar face inversion effect (with reduced responses for inverted faces and a shift from higher-level lateral occipito-temporal response peaks for upright faces towards lower-level medial-occipital response peaks for inverted faces). Unexpectedly, in both groups occipito-temporal responses were increased when focusing on the mouth as compared to the eye region, regardless of the orientation of the faces. Most importantly, between-group analyses showed significantly reduced bilateral occipito-temporal and medial occipital responses in ASD compared to TD, regardless whether faces were presented upright versus inverted or whether fixation was on the eyes or on the mouth. These implicit EEG data will be complemented with explicit behavioural emotion processing data and with face scanning patterns obtained via eye tracking.

Conclusions: Analyses show clear peaks at the oddball frequency and its harmonics in both the ASD and control group, meaning that children with ASD are capable to implicitly discriminate facial expressions. Reduced responses for inverted faces indicate the presence of the inversion effect in ASD and TDs. However, generally reduced neural oddball responses in the presence of equal baseline responses indicate that children with ASD have a lower sensitivity to fearful faces, compared to controls. This suggests a quantitative difference in emotion processing abilities.

33 **182.033** MEG Gamma Oscillations and Directional Sensitivity to Visual Motion in Children with ASD: Two Sides of the Inhibition Deficit.

T. A. Stroganova[1]*, O. V. Sysoeva*[1]*, M. S. Davletshina*[2]*, I. A. Galuta*[2]*, D. E. Goiaeva*[2]*, A. O. Prokofyev*[1] *and E. V. Orekhova*[1]*, (1)MEG-Center, Moscow University of Psychology and Education, Moscow, Russian Federation, (2)Autism Research Laboratory, Moscow University of Psychology and Education, Moscow, Russian Federation*

Background: Altered balance between excitation (E) and inhibition (I) in neural networks is thought to underlie core symptoms of ASD, including sensory processing abnormalities. In line with this hypothesis we have recently found in children with ASD a reduction of spatial suppression (SS) – a perceptual phenomenon that depends on the efficacy of inhibition in the visual cortex. If present, the E/I imbalance in ASD may affect neural gain control (i.e. the rate at which inhibition shapes neuronal firing in response to increasing excitatory input) and result in an altered pattern of intensity-related changes of gamma oscillations (30-100Hz) – the populational neural activity that is highly sensitive to the E/I ratio.

Objectives: We tested the hypothesis that the E/I imbalance is a common factor that alters both directional sensitivity to visual motion and the intensity-related changes in MEG gamma oscillations in ASD.

Methods: MEG was recorded in 43 neuro-typical (NT) boys and 36 boys with ASD aged 6-15 years. Children watched high-contrast concentric circular gratings moving at a visual angular velocity of 1.2(slow), 3.6(medium) or 6.0(fast) °/sec. To assess the neural gain control we calculated the velocity-related change in gamma response power in the 'slow' vs. 'fast' conditions – gamma suppression magnitude (gSM). Greater gSM reflects a greater reduction in the gamma power with increasing motion intensity, i.e. stronger gain control. SS has been tested in a separate psychophysical experiment wherein subjects detected the direction of motion of a small (1°) and large (12°) gratings presented for a short time. The direction discrimination deteriorates with increasing stimulus size as the result of the top-down modulated inhibition in the primary visual cortex (V1). The SS was calculated as a difference between log discrimination thresholds for the large vs. small stimuli.

Results: The power of gamma oscillations decreased with increasing visual motion. As expected, velocity-related suppression of the visual gamma response was reduced in the ASD group. The perceptual SS effect was diminished in boys with ASD mainly due to their abnormally elevated direction discrimination threshold for the small gratings. In the NT boys gSM correlated with the SS and with their discrimination threshold for the large gratings. In boys with ASD, the correlation with the SS was also present, but it was mainly due to impaired direction discrimination for the small gratings in those with low gSM.

Conclusions: The significant correlations between the neural gain regulation index and measures of motion direction sensitivity supports the hypothesis that the E/I balance is a common underlying factor for both. Our findings suggest that the normal variations in the E/I balance have a role for the top-down suppression effects associated with increasing stimulus size. In children with ASD, on the other hand, the E/I imbalance affects motion direction discrimination mainly for the small gratings suggesting impairment of the local inhibition in V1. By showing the role of E/I imbalance in abnormal directional discrimination in ASD, our findings extend the recent evidence for a broadening of the population receptive fields in V1 in ASD individuals.

34 **182.034** Motor Performance and Neural Activity of Motor Networks in Children with Autism Spectrum Disorder during Imitation of Motor Hand Actions

C. Butera[1]*, E. Kilroy*[1]*, L. A. Harrison*[1]*, S. A. Cermak*[1] *and L. Aziz-Zadeh*[2]*, (1)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy; Psychology, University of Southern California, Los Angeles, CA*

Background: Recent work has demonstrated that motor deficits are highly prevalent in children with Autism Spectrum Disorders (ASD) (Fournier et al, 2010; Ming, Brimacombe & Wagner, 2007). Additionally, imitation skills have been found to be significantly impaired in children with ASD (Williams et al. 2004). Previous imaging work has shown reduced neural activity in adolescents with ASD during imitation of hand gestures when compared to typically developing (TD) peers (Wadsworth et al, 2016). The mechanisms underlying this imitation deficit are unclear, though there may be a relationship between reduced motor skills and imitation impairments in ASD.

Objectives: (1) To compare performance on the Movement Assessment Battery for Children (MABC-2; Henderson, 2007) and MABC Checklist (Henderson, 2007) between a sample of TD children and children with ASD. (2) To assess how performance on these motor assessments correlate with neural activity in motor-related brain regions during an imitation task.

Methods: Data from 9 high-functioning participants with ASD (age 10.93 ± 1.86), and 15 TD participants (age 11.15± 1.39) were analyzed. The MABC-2 was administered and scored by an occupational therapist. MABC Checklist was completed by parents and scored by a research staff member. fMRI data was collected on a 3-T Siemens MAGNETOM Prisma scanner. In the scanner participants were instructed to imitate videos of hand actions (i.e., stapling paper, slicing bread) presented in a block design. Standard preprocessing and motion correction were applied, and whole brain comparisons between groups were made. Parameter estimates from motor regions (e.g., primary motor cortex) were extracted and correlated with motor skills.

Results: Two tailed t-tests showed both MABC-2 and MABC Checklist scores were significantly impaired in ASD compared with TD participants ($p<.001$). In the ASD group, significant correlations between MABC-2 total standard score and imitation of hand actions were found in the right precentral gyrus ($r=.67$, $p=.04$), and the left postcentral gyrus ($r=.69$, $p=.03$). However in the TD group, there were no significant correlations with MABC-2 scores and neural activity during imitation. Finally, there were no significant correlations with MABC checklist scores in either group.

Conclusions: These data suggest that in ASD, MABC-2 scores may be related to activity patterns in premotor and primary motor regions recruited during hand action imitation. This relationship is not observed in the TD group. Future directions include involving larger sample sizes, comparing to children with primary motor impairments (e.g., dyspraxia) and correlating findings with other motor and social assessments in our sample.

35

182.035 Neural Correlates of Response to Joint Attention in Toddlers with Autism Spectrum Disorder and Their Typically Developing Peers.

A. Piatti, *S. Van der Paelt, P. Warreyn and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background:

Joint attention development is atypical in children with autism spectrum disorder (ASD). As far as initiation of joint attention is concerned, the literature points unanimously to an impaired development in individuals with ASD, whereas there is less agreement concerning response to joint attention, as observational methods alone do not consistently detect differences between children with ASD and typically developing (TD) children. On the other hand, toddler studies using eye-tracking, as well as neuroimaging research in older children suggest that, in spite of a preserved gaze-following ability, response to joint attention in ASD and TD children might be qualitatively different.

Objectives:

With this study we have been investigating the neural correlates of joint attention response in toddlers with ASD and their TD peers using fNIRS, to gain a deeper insight into joint attention development in ASD.

Methods:

We are planning to test 20 toddlers with ASD and 20 TD toddlers. 40% of total data has been collected to date, as we have tested 5 toddlers with ASD (all boys, mean age 3.13 ± 0.63) and 13 TD controls (6 boys, mean age 2.99 ± 0.68). Participants watched fragments of age-appropriate cartoons (duration: 11-13 s) interspliced by a static baseline (duration: 13-15 s). In 50% of trials, the start of the cartoon is signalled by the experimenter (joint attention condition). In the other 50% of trials, the attentional cue is a computer sound and the experimenter looks away from the screen while the cartoon plays.

Results:

Preliminary results (ASD: 25% of data analysed, TD: 65% of data analysed) show group differences over the effects of joint attention over dorsomedial prefrontal cortex (DMPFC) and right temporo-parietal junction (rTPJ). Over DMPFC we found an ATTENTION x GROUP interaction in the 0-5 s time-window (F(1,16) = 11.719, p =.002). Follow-up analysis shows that effects of joint attention were only present in the TD group (F(1,12) = 16.265, p = .001). Over rTPJ, the ATTENTION x GROUP interaction approaches significance in the 10-15 s time-window (inferior rTPJ/Brodmann area 41: F (1, 14) = 4.348, p =.059; superior rTPJ/Brodmann area 40: F (1, 13) = 4.163, p =.061). Follow-up shows that the interaction is due to a lack of activation during joint attention in the ASD group (p >.05).

Conclusions:

We found atypical activation in children with ASD during response to joint attention in areas (DMPFC and rTPJ) that are involved both in general attentional orienting and in mentalisation. The timing of the activation over these areas suggests that children with ASD do orient to social attention cues, but this process is slower for them than for their TD peers, which in turn may impair their ability to infer the social intention of the initiator of joint attention.

36

182.036 Neural Representations of Facial Identity and Emotional Expressions in Young Adults with and without ASD

M. H. Hendriks[1,2]*, C. Dillen*[3]*, N. Daniels*[2,3]*, J. Bulthé*[1]*, F. Pegado*[1]*, J. Steyaert*[2,4]*, H. Op de Beeck*[1] *and B. Boets*[2,4]*, (1)Department of Brain and Cognition, KU Leuven, Leuven, Belgium, (2)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium, (3)Department of Rehabilitation Sciences, KU Leuven, Leuven, Belgium, (4)Center for Developmental Psychiatry, KU Leuven, Leuven, Belgium*

Background: “Why didn’t you say hello? One of your classmates just passed by.” Most people are experts in the recognition of faces and facial expressions. However, individuals with autism spectrum disorders (ASD) often have difficulties processing faces, both in recognizing facial identity -especially when they don’t expect seeing someone- and in interpreting feelings based on facial expressions. Even though face processing difficulties are included in the diagnostic criteria of ASD, the empirical evidence is mixed.

Objectives: The goal of this study was to quantify the quality of neural representations with regard to facial identity and emotional expression. Although there might not be a large difference between the groups at a behavioral level, we studied whether there may be differences at the brain level between individuals with and without ASD while looking at faces with different identities and different facial expressions.

Methods: 52 young adults (age 17-23 years) participated in this study. Data were acquired while participants were lying in a 3T MRI scanner. They were looking at short movies of a dynamic face, which gradually transitioned from a neutral facial expression to an emotional facial expression. The movies comprised four different identities and six different emotions. Participants had to push a button whenever the current movie differed from the previous one, regardless of this change occurring in identity or expression. 45 Individuals were included in the analyses (21 ASD, 24 control participants). We tested whether different emotions and identities could be consistently classified and differentiated based on neural activity patterns in a series of face selective brain regions. More specifically, we performed multi-voxel pattern analyses (MVPA) based on a support vector machine to investigate whether different emotions and identities can be decoded on the basis of their neural activation pattern.

Results: Initial analyses show that different facial identities can be reliably distinguished in posterior temporal cortex, superior temporal sulcus, inferior occipital cortex, and primary visual cortex, in both groups. Likewise, different facial expressions can be decoded in these same brain regions. Thus far, our analyses suggest that there are no significant differences in neural response patterns between these two groups.

Conclusions: Neural activation patterns can be used to reliably decode facial identity and facial expression in occipito-temporal brain regions, both in adults with ASD and in neurotypical controls. The initial findings lead us to conclude that there are no detectable differences in the quality of the neural representations and activation patterns between individuals with and without ASD. At the conference, we will present some more fine-grained analyses, including associations with a large battery of behavioral tasks assessing face processing.

182.037 Neural Representations Underlying the Observation of Interpersonal Socio-Affective Touch in Adults with and without

Autism Spectrum Disorder

[1], B. Boets[2] and H. Op de Beeck[1], (1)Department of Brain and Cognition, KU Leuven, Leuven, Belgium, (2)Center for Developmental Psychiatry, KU Leuven, Leuven, Belgium

---

Background: Humans can easily grasp the affective meaning of socio-affective touch when observing other`s interactions. This ability may be linked to theory of mind (ToM) and somatosensory resonance. For example, when we see one person consoling another by giving a hug, we can understand the meaning of the hug and imagine its warmth. However, individuals with autism spectrum disorder (ASD) exhibit impairments in the use of nonverbal communication such as social and reciprocal touch, which gives them a huge disadvantage in social interactions. Despite the importance of touch in social communication and the pervasiveness of this aversion in ASD, surprisingly little is known about touch communication impairments in ASD, ultimately limiting diagnostic tools and therapeutic interventions.

Objectives: The present study aims to develop an experimental paradigm to address where and how socio-affective touch communication is represented in the brain of individuals with and without ASD. In particular, we examined the involvement of ToM and somatosensory resonance networks in processing observed social touch communication in the neurotypical (NT) brain in order to compare it with the brain processing of individuals with ASD.

Methods: A novel socio-affective touch database of 39 videos, covering pleasant (e.g., hugging a person), and unpleasant social touch (e.g. slapping a person), was used as stimuli (Figure 1). First, 21 NT participants evaluated valence and arousal of each video from which we extracted a group affective similarity matrix. Subsequently, the participants underwent fMRI scans during which they watched the same videos and performed an orthogonal task. Importantly, the participants also received positive and negative touch on their ventral forearms in the scanner in order for us to capture individual touch sensitive cortices as regions of interest (ROI). The social brain regions, including the temporoparietal junction (TPJ) known as a ToM area, were also included as ROIs. Using correlational multi-voxel pattern analysis (MVPA) methods, we generated a neural similarity matrix in each ROI. Lastly, multiple regression analysis was implemented in order to predict the neural data based on the perceived affect (combination of valence and arousal) of socio-affective touch.

Results: The results from pleasantness and arousal ratings suggest that positive touch was perceived as pleasant and negative touch as unpleasant with high inter-subject consistency on ratings. For example, the participants perceived a passionate hug as pleasant and highly arousing and a nudge as unpleasant and mildly arousing. Importantly, this affective meaning of touch was well represented in social brain areas and some parts of touch sensitive somatosensory regions. However, neural patterns in visual cortices as control regions could not be explained by perceived affect of observed touch communication (Figure 2).

Conclusions: Our findings highlight the involvement of perspective taking and somatosensory resonance when observing other`s affective touch interactions. Our results provide pivotal insights on neural mechanisms underlying the observation of interpersonal socio-affective touch in NT individuals. We are currently administering the same paradigm in 23 matched adults with ASD. At the conference we will be able to present group comparisons for the behavioral and neural data.

182.038 Neurophysiological Correlates of Altered Motivation Towards Social and Non-Social Stimuli in ASD

C. Luckhardt[1]*, H. Althen*[2]*, J. Kopf*[3] *and C. M. Freitag*[1]*, (1)Autism Research and Intervention Center of Excellence Frankfurt, University Hospital Frankfurt, Frankfurt am Main, Germany, (2)Autism Research and Intervention Center of Excellence Frankfurt, Goethe Universitat Frankfurt am Main, Frankfurt am Main, Germany, (3)Dept. of Psychiatry, Psychosomatic Medicine and Psychotherapy Frankfurt, Goethe Universitat Frankfurt am Main, Frankfurt am Main, Germany*

Background:

In recent years the social motivation hypothesis of ASD (Chevallier, 2012) has gained popularity. Neuroimaging studies do not only suggest that individuals with ASD perceive social stimuli as less salient (Delmonte, 2012), but also that they show increased motivation towards non-social stimuli (Cascio, 2013). Directly comparing the neural response to social emotional versus non-social stimuli is therefore of great interest. The late positive potential (LPP) is a well suited neurophysiological measure for this purpose, as it represents motivational and attentional processes during the perception of social stimuli (Schupp et al. 2000). It is sensitive to the emotional content of stimuli and perceived relevance, and thereby related to the allocation of attentional resources (Schupp et al., 2004; Hajcak and Olvet, 2008; Ferrari et al., 2010).

Objectives:

The objective was to compare neural correlates of motivation and attention for social and non-social stimuli between children and adolescents with ASD and healthy controls.

Methods:

Participants viewed images of positive, negative and neutral emotional scenes involving humans, as well as neutral pictures of plants, while EEG was recorded. A one-back memory task was performed to sustain attention. Afterwards ratings of valence and arousal were obtained for all stimuli. The LPP was analyzed for each stimulus category as an area measure of 300-600 ms post stimulus onset at central, left and right posterior-parietal electrode clusters. LPP area measures and valence and arousal ratings were compared between groups using repeated measures ANOVAs (Between: Group ASD vs. CON, Within: Condition positive/negative/neutral/plant).

Results:

Analysis of a preliminary sample of 20 individuals with ASD and 10 controls (which were matched for age and IQ) indicate that children with ASD perceived negative emotional images as less arousing (p=.009), while plant pictures were rated as more arousing compared to controls (p=.040). Valence ratings also showed that the ASD group rated the negative emotional pictures as less negative (p=.040), and found plant stimuli just as pleasant as positive emotional stimuli (p_{ASD} =1.0, p_{CON}=.005). Looking at the LPP a group by condition interaction was found in the right hemisphere (F[3,84]=2.8; p=.043). Post-hoc tests suggested that this might have been due to higher LPPs for plant stimuli in the ASD compared to the control group (p=.091, $Mean_{ASD}$=5714.3±2995.5 µV*ms; $Mean_{CON}$=3812.6±2362.2 µV*ms).

Conclusions:

These preliminary results indicate that individuals with ASD do indeed perceive social emotional and non-social stimuli differently. This pattern is also confirmed by an increased LPP response for non-social stimuli. These findings expand existing evidence by showing that the LPP is not only increased for non-social stimuli that are of special interest to individuals with ASD (Benning, 2016), but also for other seemingly random non-

social objects like plants.

39 **182.039** Oxytocin´s Effect on Empathy in Autism – Neural Activation As a Function of the Oxytocin Receptor Gene Variation.

S. Stroth[1]*, A. K. Wermter*[2]*, S. Krach*[3]*, M. Haberhausen*[2]*, F. Paulus*[4]*, T. Stehr*[5]*, A. Mayer*[6] *and I. Kamp-Becker*[7]*, (1)Philipps University Marburg, Marburg, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University of Marburg, Marburg, Germany, (3)Center of Brain, Behavior and Metabolism, Luebeck, Germany, (4)Philipps-University Marburg, Marburg, Germany, (5)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Marburg, Germany, (6)Lübeck University, Lübeck, Germany, (7)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Schutzenstr 49, Germany*

Background: Individuals with autism spectrum disorder have deficits in the capacity to intuitively represent their own and others' mental states which is associated with impairments in social interaction and communication. Although ASD is considered a neurobiological disorder, primary treatments nowadays consist of psychological and educational interventions to address the core deficits related to the disorder. Pioneering but strong evidence suggests that oxytocin (OXT) has the potential to enhance motivation and attention to social cues in patients with ASD, facilitating the processing of social emotions, social reward and higher cognitive functions such as empathy and Theory of Mind. Beyond a therapy effect, it has been demonstrated that genetic factors can influence an individuals response to OXT, either by directly acting on OXT genes or via the regulation of genes in pathways related to OXT.

Objectives: In view of the individual variability in OXT response, the consideration of individual factors such as genetic variations is warranted in studies investigating the efficacy of OXT administration in ASD treatment. Therefore, we aim to analyse the effect of genetic variation in the oxytocin-receptor-gene (*OXTR*) on the neural pathways involved in social affect in a group of persons with ASD.

Methods: We examined in a placebo-controlled, double blind, randomized fMRI study (including three experiments to examine social affect on distinct levels) with crossover-design the effect of oxytocin in dependence of a specific genotype. 26 young men (Age mean 23,0±4,4; IQ mean 107,9±18,2) who matched the DSM IV criteria for ASD and who had a confirmed ICD-10 diagnosis of high-functioning ASD took part. 15 participants had a validated variation in the *OXTR* and 10 participants were without the risk allele.

Results: On the behavioural level we can observe differential effect of OXT in dependence of the *OXTR*. Participants with the variation in the *OXTR* show a significant increase of social affect. Further differences on underlying brain networks will be analysed and presented

Conclusions: The consideration of genetic variation in the *OXTR* seems to have the potential to identify those participants with ASD who get the most out of OXT treatment.

40 **182.040** Relations between Frontal Gamma Power, Socioeconomic Status, and IQ Among Adolescents with and without ASD

K. M. Rivera[1]*, A. J. McVey*[1]*, H. K. Schiltz*[1]*, A. D. Haendel*[2]*, S. Pleiss*[3]*, A. Carson*[4]*, B. Yund*[5] *and A. V. Van Hecke*[6]*, (1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Great Lakes Neurobehavioral Center, Edina, MN, (4)Baylor College of Medicine, Houston, TX, (5)Psychology, University of Wisconsin Milwaukee, Milwaukee, WI, (6)Psychology, Marquette University, Milwaukee, WI*

Background: Research suggests that socioeconomic status (SES) has implications for cognitive development (e.g., executive functioning and IQ) among typically developing (TYP) children (Farah et al., 2006), namely that children from lower SES backgrounds experience difficulties in these cognitive domains. Studies have found that the cognitive impact of SES can be observed on a neurological level through electroencephalogram (EEG) in the frontal gamma band (Tomalski et al., 2013); this area has been linked with higher-order cognitive processes (Gou, Choudhury, & Benasich, 2011). Lower gamma power has been examined in individuals with ASD (Maxwell et al., 2015), however, the relation of SES, frontal gamma power, and IQ among a sample of youth with ASD has not been examined.

Objectives: The objective of the present study was to evaluate the relations between SES, EEG frontal gamma power, and IQ among adolescents with and without ASD. It was hypothesized that frontal gamma power and IQ would be positively related to SES.

Methods: Fifty-nine adolescents with ASD and 18 without ASD (TYP), aged 11-17, participated. Participants were from a social skills intervention study; data here was from the pretest (before intervention) time point. Participants completed a three-minute resting state EEG paradigm from which frontal gamma power was calculated and the KBIT-2 (Kaufman & Kaufman, 2004) to obtain IQ. Parents/primary caregivers completed a demographic form that asked about their own education and household income, which were used as separate indicators of SES.

Results: No significant differences in demographic variables were found between groups. Spearman correlations revealed no significant associations between SES and frontal gamma power within either group for income (ASD: $r_s(57)=-.020$, $p=.880$; TYP: $r_s(18)=-.202$, $p=.421$) or education (ASD: $r_s(59)=-.203$, $p=.124$; TYP: $r_s(18)=.045$, $p=.860$). There was a significant association between SES and IQ for education in both groups (ASD: $r_s(59)=.259$, $p=.047$; TYP: $r_s(18)=.614$, $p=.007$) and income in the TYP (ASD: $r_s(57)=.122$, $p=.366$; TYP: $r_s(18)=.488$, $p=.040$). Pearson's correlations were conducted to examine the association between frontal gamma power and IQ within each group; a negative link was found in the ASD ($r_s(59)=-.266$, $p=.042$), but not the TYP, group.

Conclusions: Contrary to hypotheses, results showed no relation between frontal gamma power and SES among adolescents with or without ASD. This is in contrast to previous work that identified association between brain development and SES among typically developing children (Noble, Houston, Kan, & Sowell, 2012). Additionally, there was a negative link between IQ and frontal gamma power in the ASD group but no relation in the control group. This finding could be from the atypical gamma power found in individuals with ASD. Paradoxically, IQ was related to education among both groups which suggests that SES might influence certain cognitive processes in ASD. Of note, the current sample was comprised of participants from relatively high SES and, thus, links between SES and neurological functioning may have been undetectable due to the small number of participants in the lower SES categories.

41 **182.041** Resting-State Functional Thalamo-Cortical Overconnectivity Is Associated with Block Design Peak in Autism

E. Danis[1]*, F. Samson*[2]*, E. B. Barbeau*[3]*, A. Boré*[4] *and I. Soulieres*[5]*, (1)University of Quebec in Montreal, Montréal, QC, Canada, (2)McGill University, Montreal, QC, Canada, (3)Cognitive Neuroscience Unit, Montreal Neurological Institute, McGill University, Montreal, QC, Canada, (4)Centre de recherche de l'Institut universitaire de gériatrie de Montréal, Montreal, QC, Canada, (5)Psychology, University of Quebec in Montreal, Montréal, QC, Canada*

Background: The thalamus relays sensory information to the cortex, but is also implicated in cognition trough cortico-thalamo-cortical connections (Sherman, 2012). Thus, this subcortical structure's intrinsic activity might have a role in autistics' atypical perceptual processing, which is related to their superior performance in visual tasks (Falter et al., 2013), like the Block Design (BD) task (Muth et al., 2014). There are a few reports of thalamic differences between autistic and non-autistic individuals with regards to its structure, activity and connectivity, but we do not have yet a clear and specific pattern of thalamic differences and their associations with cognitive performances.
Objectives: To investigate intrinsic functional connectivity involving the thalamus during rest in autistic versus non-autistic individuals and to verify the presence of associations with cognitive performance.

Methods: Thirty-five autistic (31 males) and 43 non-autistic (42 males) individuals underwent a resting state fRMI scan (Siemens Tim Trio 3T). Groups were matched on age (14-38 years; Autistics *M*=21.3, *SD*=6.1; Non-autistics *M*=22.6, *SD*=5.3), Wechsler Performance Intelligence Quotient (IQ) (Autistics *M*=106.0, *SD*=12.4; Non-autistics *M*=104.8, *SD*=13.4), Raven's Progressive Matrices (RPM) percentiles (Autistics *M*=72.2, *SD*=23.7; Non-autistics *M*=72.4, *SD*=22.3) and manual preference. Seed-to voxel analyses were performed between the thalamic nuclei and the rest of the brain in both groups. Connectivity values of regions showing significant differences between autistics and non-autistics were then correlated with the participants' Wechsler Full-scale, Verbal and Performance IQ, their RPM percentile and their BD scaled score and peak (the difference between the BD scaled score and the mean of all other Wechsler subtests).

Results: A pattern of greater thalamo-cortical connectivity was observed in autistic compared to non-autistic participants. Specifically, the autistic group presented stronger connections between the thalamus and the fusiform gyrus, the superior, middle and inferior temporal gyri, the temporal pole, the superior occipital gyrus and the inferior frontal regions than the non-autistic group. Interestingly, these over-connections were observed for a specific thalamic region, the medio-dorsal nucleus. The analysis of the correlations between the connectivity values of each of the cortical regions showing stronger connections with the medio-dorsal nucleus in the autistic relative to non-autistic participants with cognitive measures revealed significant positive correlation with BD peak values.

Conclusions: A pattern of stronger intrinsic connectivity between thalamus and posterior regions was observed in autistic participants relative to non-autistic participants. This stronger connectivity mainly involved a specific region from the thalamus, the medio-dorsal nucleus. The medio-dorsal thalamic nucleus typically has reciprocal connections with the prefrontal cortex and has a role in executive functions and learning (Ferguson & Gao, 2014). Its resources could be partially reallocated from the prefrontal cortex to the occipito-temporal regions in autistic individuals (as they exhibited stronger thalamo-occipitotemporal connectivity). As the strength of these connections correlates with visuospatial performance, this thalamo-occipitotemporal enhanced connectivity seen in autistic individuals may contribute to their visuospatial and cognitive strengths.

42 **182.042** Sex Differences in Interhemispheric Resting State Functional Connectivity in Autism Spectrum Disorder in Early Childhood

J. K. Lee[1], *B. Heath*[1], *A. L. Hechtman*[2], *C. Gohring*[3], *K. Huynh*[3], *D. G. Amaral*[1], *S. Ozonoff*[2] *and C. W. Nordahl*[1], *(1)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (3)UC Davis MIND Institute, Sacramento, CA*

Background: Sex differences in the neuropathology of autism spectrum disorder (ASD) are currently poorly understood. While prior research reported sex and ASD related differences in diffusion properties and organization of the corpus callosum in pre-school age children (Nordahl et al., 2015), these interhemispheric connectivity differences have not been examined using resting-state functional magnetic imaging (rfMRI).
Objectives: The current research examines sex-differences in interhemispheric resting state functional connectivity in preschool aged children with and without ASD, and how individual differences ASD symptom severity relates to interhemispheric connectivity.

Methods: The sample included 119 children with ASD (86 male, 33 female) and 68 age-matched typically developing (TD) controls (40 male, 28 female) (mean age 3.7 years). Diagnostic assessments for ASD were carried out by expert clinicians using the ADOS and ADI-R. Structural and resting state EPI BOLD images were acquired during natural nocturnal sleep. Resting state images were preprocessed using tools from AFNI, FSL, and ANTS in the Configurable Pipeline for the Analysis of Connectomes (C-PAC; Craddock et al., 2013). In brief, EPI images were time-shifted, motion corrected, and band-pass filtered (.008 < f < .08 Hz). Volumes with frame-wise displacement greater than 0.25mm were scrubbed. EPIs were then co-registered to the participant's structural T1-weighted image and then to symmetric MNI space, and smoothed at 6 mm FWHM. Interhemispheric connectivity was assessed using voxel-mirrored homotopic connectivity (VMHC). Cluster based correction for multiple comparisons was carried out using Gaussian Random Field theory using FSL (Z >2.58, p_{GRF} <.05). For each interaction cluster, mean interhemispheric connectivity was extracted for each participant to test simple effects and slopes; reported p-values for these tests are adjusted for multiple comparisons using Bonferroni.
Results:

Preliminary results reveal atypical interhemispheric functional connectivity in both boys and girls with ASD. Both males and females with ASD exhibit decreased interhemispheric connectivity between left and right posterior cingulate and precuneus cortices relative to TD (*p* = .01), with a cluster in the precuneus exhibiting a larger decrease in ASD males relative to TD males than do ASD females relative to TD females (Interaction: *p* = 1.0e-4). Reductions in interhemispheric connectivity relative to TD were also observed in paracingulate cortex and frontal operculum in males (*p*s ≤ .002). Greater ADOS severity scores predict greater interhemispheric connectivity in the cerebellum in females (b = .12, *p* = .048), but not males (b = -.07, *p* = .12), (interaction: *p* = .006). Greater ADOS severity scores predict decreased interhemispheric connectivity in two clusters in precuneus and superior temporal gyrus in males (bs = ≤ -.07, *p*s ≤ .001), but positively in the middle temporal gyrus for females (b = .08, *p* = .03) (interactions: *p*s ≤ 3.1e-5). These results suggest that the neural phenotype of ASD in young children is differentially presented in males and females compared to their respective typically developing peers.

Conclusions: These preliminary data suggest that females and males with ASD have partially dissimilar patterns of interhemispheric functional connectivity.

43 **182.043** Sex-Specific Fetal Programming Impact of Testosterone on Later Developing Intrinsic Functional Connectivity between Social Brain Default Mode Subsystems

M. V. Lombardo[1], *B. Auyeung*[2], *T. Pramparo*[3], *A. Quartier*[4], *M. C. Lai*[5], *R. Holt*[6], *J. Waldman*[6], *A. N. Ruigrok*[6], *N. Mooney*[6], *P. Kundu*[7], *E. Bullmore*[6], *J. L.*

Mandel[4], A. Piton[4] and S. Baron-Cohen[8], (1)University of Cyprus, Nicosia, Cyprus, (2)University of Edinburgh, Edinburgh, United Kingdom, (3)Univeristy of California, San Diego, La Jolla, CA, (4)Institut de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch, France, (5)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (6)University of Cambridge, Cambridge, United Kingdom, (7)Translational and Molecular Imaging Institute, Icahn Institute of Medicine at Mt. Sinai, New York, NY, (8)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

---

Background: Many early-onset neurodevelopmental conditions such as autism affect males more than females and affect corresponding domains such as social cognition, social-communication, language, emotion, and reward. Testosterone is well-known for its role as a sex-related biological mechanism that affects such conditions and domains of functioning. Developmentally, testosterone may sex-bias early fetal brain development by influencing early neuronal development and synaptic mechanisms behind cortical circuit formation, particularly for circuits that later develop specialized roles in such cognitive domains.

Objectives: As a model for sex-specific mechanisms involved in autism, we investigate how fetal testosterone (FT) biases neural circuitry development in a sex-specific manner. We also examined the question of how androgens directly affect gene expression in these circuits during early prenatal periods of brain development.

Methods: Age-matched neurotypical male and female adolescents (n=32 per group, 13.22-17.18 years) were scanned with resting state fMRI (rsfMRI) on a multi-echo EPI sequence at 3T. FT was measured with radioimmunoassays on amniotic fluid samples collected during midgestation. rsfMRI data were preprocessed using multi-echo independent components analysis (ME-ICA). Functional connectivity between neural circuits was measured utilizing group-ICA and dual regression as implemented in FSL. Between-component connectivity was estimated with partial correlations (ridge regression) using FSLNets. To gain insight into how androgens affect gene expression in a model of human prenatal neurodevelopment, we further examined how gene expression changes in human neural stem cells (hNSC) after treatment with a potent androgen, dihydrotestosterone (DHT) (a re-analysis of data from Quartier et al., in revision, *Biol Psychiatry*). We then tested for enrichment between DHT-dysregulated genes and genes that show spatial patterns of gene expression that are similar to the default mode network. Spatial gene expression similarity is measured using the Neurosynth Gene Expression Decoding feature on the Allen Institute Human Brain Gene Expression Atlas data.

Results: Variation in fetal testosterone (FT) exerts sex-specific effects on later adolescent functional connectivity between social brain default mode network (DMN) subsystems. Increasing FT is associated with later dampening of functional connectivity between DMN subsystems in males ($r = -0.69$), but has no effect in females ($r = 0.02$). This difference between sexes was highly significant ($z = 3.35$, $p = 7.88e-4$). No other circuits were identified at FDR $q<0.05$ as affected by FT in a sex-specific manner. Within hNSCs, DHT dysregulates genes involved in early neurodevelopmental biological processes such as neurogenesis, cell differentiation, regionalization, and pattern specification. Gene sets with a high degree of spatial expression similarity in the adult brain to cortical midline DMN circuitry are also highly enriched in DHT-dysregulated genes (OR = 1.88, $p = 0.000002$). These DMN-related and DHT-dysregulated genes are highly enriched (fold enrichment > 5) in synaptic biological processes.

Conclusions: This work highlights sex-specific prenatal androgen influence on human social brain DMN circuitry and is of high-relevance to male-biased conditions affecting social brain development such as autism. Prenatal androgens may act as male-specific influences on DMN cortical circuit formation and maintenance by affecting genes involved in both early neurodevelopmental processes (e.g., neurogenesis, cell differentiation) and later synaptic processes.

182.044 Spontaneous and Explicit Mentalizing in Adults with Autism Spectrum Disorder: An Fmri Study

***A. D. Nijhof**[1], L. Bardi[2], M. Brass[3] and J. R. Wiersema[4], (1)Institute of Psychiatry, King's College London, London, United Kingdom, (2)Ghent University, Ghent, Belgium, (3)Department of Experimental Psychology, Ghent University, Ghent, Belgium, (4)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background:

The socio-communicative difficulties of individuals with autism spectrum disorder (ASD) are hypothesized to be caused by a specific deficit in the ability to represent one’s own and others’ mental states, referred to as Theory of Mind or mentalizing. However, many individuals with ASD show successful performance on explicit measures of mentalizing, and for this reason, the deficit is thought to be specific to spontaneous mentalizing. While there is initial behavioral support for this hypothesis, spontaneous mentalizing in ASD has not yet been studied at the neural level. Recent findings in neurotypicals indicate a crucial role for the right temporoparietal junction (rTPJ) in both explicit and spontaneous mentalizing.

Objectives:

The goal of the current study was to investigate brain activation during both explicit and spontaneous mentalizing in adults with ASD and a neurotypical control group, by means of fMRI. Based on our hypothesis of a core mentalizing deficit in ASD associated with rTPJ abnormalities, decreased rTPJ activity was expected for both forms of mentalizing in adults with ASD.

Methods:

A group of 24 adults with ASD and 21 neurotypical controls carried out a spontaneous and an explicit version of the same mentalizing task. They watched videos in which both they themselves and another agent formed a belief about the location of an object (belief formation phase). Only in the explicit task version participants were instructed to report the agent’s belief on some trials.

Results:

At the behavioral level, no group differences were revealed in either of the task versions. A planned region-of-interest analysis of the rTPJ showed that this region was more active for false- than for true-belief formation, independent of task version, especially when the agent’s belief had a positive content (when the agent was expecting the object). This effect of belief was absent in adults with ASD. A whole-brain analysis revealed reduced activation in the anterior middle temporal pole in ASD for false- versus true-belief trials, independent of task version.

Conclusions:

Our findings suggest neural differences between adults with ASD and neurotypical controls both during spontaneous and explicit mentalizing, and indicate the rTPJ to be crucially involved in ASD. Moreover, the possible role of the anterior middle temporal pole in disturbed mentalizing in ASD deserves further attention. The finding that these neural differences do not necessarily lead to differential performance warrants further research.

45 **182.045** The Dup15q Syndrome EEG Signature Resembles the EEG Effect of GABA-a Modulators

J. Frohlich[1], *S. Huberty*[2], *V. Saravanapandian*[1], *C. DiStefano*[1], *S. Jeste*[3] *and J. F. Hipp*[4], *(1)University of California Los Angeles, Los Angeles, CA, (2)Mcgill University, Montreal, QC, Canada, (3)University of California, Los Angeles, Los Angeles, CA, (4)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, Basel, Switzerland*

Background:
Duplication 15q11.2-q13.1 (Dup15q) syndrome is a neurogenetic syndrome that is highly penetrant for autism spectrum disorder (ASD), as well as intellectual disability (ID) and epilepsy. Excess beta (12-30 Hz) oscillations in the electroencephalogram (EEG) are the distinguishing electrophysiological feature of Dup15q syndrome that may relate to clinical traits [Frohlich et al, 2016]. It is uncertain to what extent this EEG signature relates to expression of gamma-aminobutyric acid-A receptor (GABAaR) genes *GABRA5*, *GABRB3*, *GABRG3* in the duplicated 15q11.2-q13.1 locus.

Objectives: We sought to compare the Dup15q syndrome power spectrum to spectral changes induced by the benzodiazepine midazolam in healthy volunteers (HV). Midazolam and other benzodiazepines are non-selective GABAaR positive allosteric modulators (PAMs) that enhance the inhibitory chloride current through the GABAaR in the presence of GABA. In this manner, midazolam may provide an acute reference model for the electrophysiological effects of GABAaR gene overexpression as presumed in Dup15q syndrome.

Methods: Spontaneous EEG recordings were obtained from n = 24 children with Dup15q syndrome with ages spanning from 16 months to 14 years. These recordings were directly compared to those from 1) n = 14 age-matched typically developing (TD) children, 2) n = 14 age-and-IQ-matched children with non-syndromic ASD. Power spectral densities (PSDs, 1-32 Hz) were obtained using a Morlet wavelet transform and normalized to give relative power. The analysis was unbiased with respect to directionality, frequency band, and electrode location and accounted for multiple comparisons using cluster randomization statistics. Group differences in spectral power were compared to changes induced by midazolam in n = 12 healthy adult volunteers 1 hour following a 5mg oral administration relative to pre-dose baseline.

Results: Power differences between children with Dup15q syndrome and control groups strongly resembled spectral changes induced by midazolam in HV. Specifically, the Dup15q cohort exhibited a greater than 100% increase in relative beta power mirroring a 20-40% increase induced by midazolam in HV. Statistically significant ($p < 0.05$) clusters encompassing all channels revealed decreased power peaking at 9.5 Hz and increased power peaking at 22.6 Hz in Dup15q syndrome relative to pooled controls. A subset of electrodes belonged to a cluster of decreased power peaking at 3.8 Hz in Dup15q syndrome.

Conclusions: Spectral power anomalies identified in Dup15q syndrome are consistent with a pattern of increased high frequency oscillations and decreased low frequency oscillations reported in healthy adult volunteers challenged with midazolam and other benzodiazepine compounds. While some caution is required comparing results from adults to children, we nonetheless suggest an electrophysiological isomorphism between the Dup15q syndrome EEG biomarker and midazolam-induced EEG changes. Considering that children with Dup15q syndrome have 1) duplications of GABAaR subunit genes and 2) EEG changes mirroring those induced in HV by the GABAaR PAM midazolam, we conclude that EEG anomalies in Dup15q syndrome likely relate to overexpression of GABAaR genes. In fact, previous work [Urraca et al, 2013] has reported such EEG anomalies in patients with paternal 15q11.2-q13.1 duplications, thus obviating the paternally silenced gene *UBE3A* as the cause of such EEG patterns.

46 **182.046** The Influence of Age and ASD on Verbal Fluency Network Differences

L. C. Baxter[1], *B. B. Braden*[2], *A. Nespodzany*[3], *E. Wood*[3] *and C. J. Smith*[4], *(1)Radiology, Barrow Neurological Institute, Phoenix, AZ, (2)College of Health Solutions, Arizona State University, Tempe, AZ, (3)Barrow Neurological Institute, Phoenix, AZ, (4)Southwest Autism Research & Resource Center, Phoenix, AZ*

Background: Language functioning is variable in autism, ranging from nonverbalism in more severely affected individuals to problems with pragmatic aspects of language comprehension as well as other aspects of language processing in high functioning individuals. Aging also influences word production, in part due to decline in processing speed and changes in executive functioning.
Objectives: To investigate the influence of age and autism on fluency and its underlying brain networks.

Methods: Participants were recruited through the community and underwent screening for ASD prior to cognitive and MRI assessments. Inclusion/exclusion criteria included IQ > 80, male, and general good health. Participants included older (n =21; M=53; SD=8; 40-70) and younger (n = 18, M=21; SD=3; 18-25) individuals with ASD and age- and IQ-matched Typically Developing (TD) participants (older: n = 20, M=50; SD=7; 40-64; younger: n = 13, M=21, SD=3; 18-25). Outside the scanner, participants performed the Controlled Oral Word Association Test (COWAT) and participants also performed a fluency task modified for functional MRI (fMRI) task on a Philips 3 Tesla scanner. Group ICA was first used to visualize any network differences across groups, and nodes from significant networks were extracted from group data for further analysis using SPSS (v19).

Results:
The young adult ASD group had a lower mean COWAT score; therefore, the COWAT covariate was used for fMRI analyses. There were no significant group differences for fMRI task performance measured by mean number of words produced. All groups produced a network involving left inferior frontal cortex (LIFC), in the general area often termed “Broca’s area” that is critical for expressive language. Other networks reflecting increased activity during word generation included the right cerebellum, anterior cingulate, left hippocampus. Precuneus/posterior cingulate regions showed greater engagment during the baseline condition. Not all groups utilized these regions to the same extent when performing the fluency task, despite all groups having very similar task performance. Some regions contributing to this fluency task showed clear aging effects, while others showed group differences. The left hippocampus was far less engaged in the fluency task for both older ASD and TD individuals; in contrast, both older and younger adult ASD groups showed less cerebellar activation compared to the TD groups. No significant age by ASD interactions were observed, but among older individuals only, significant increased engagement of Broca’s area was observed in the ASDs compared to the TD group, possibly reflecting compensation for other weaknesses.

Conclusions: We found that both age and the presence of ASD influenced brain networks engaged during a fluency task. With our current sample, we did not find any significant age-by-group interactions, but a trend that older individuals with ASD may utilize Broca’s area to a greater degree to compensate for other network weaknesses. Interestingly older adults use less memory-related regions than their younger counterparts, while individuals with ASD generally tend to engage the cerebellum less than TDs.

182.047 The Role of Biological Sex and Age in the Intrinsic Functional Properties of Males and Females with Autism

D. L. Floris[1]*, M. C. Lai*[2]*, M. P. Milham*[3] *and A. Di Martino*[4]*, (1)Donders Centre for Cognitive Neuroimaging, Nijmegen, Netherlands, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Institute for Pediatric Neuroscience, NY, NY, (4)The Child Mind Institute, New York, NY*

Background: The male preponderance in the prevalence of autism spectrum disorder (ASD) has sparked research into its sex differences. While sex differences have been reported to vary with age in cognitive-behavioral studies of typical and atypical development, very little is known about neural sex differences across neurodevelopment in ASD. Initial resting-state functional magnetic resonance imaging (R-fMRI) findings suggest that females and males with ASD present with different neurophenotypes (Alaerts *et al.*, 2016, Ypma *et al.*, 2016). However, no study has considered developmental sex differences in the intrinsic functional brain of those with ASD.

Objectives: We aimed to explore the role of biological sex and age in the intrinsic functional properties of the brain in males and females with ASD relative to neurotypical males and females.

Methods: We leveraged the combined large-scale Autism Brain Imaging Data Exchange (ABIDE I and II) repositories to select de-identified, low-motion R-fMRI from the publically available ABIDE repositories to include females with ASD aged 5 to 30 years, IQ- and age-matched males with ASD as well as age-matched neurotypical control males and females. We examined five voxel-wise R-fMRI metrics that have been found to be affected in ASD and to have distinct patterns by sex. R-fMRI data was preprocessed using the Configurable Pipeline for The Analysis of Connectomes. We set a general linear model at each voxel assessing the main effect of sex, age and diagnosis and their three-way interaction while accounting for head motion, acquisition sites and mean measure signal. We employed Gaussian random field theory correction with stringent statistical thresholds ($Z \geq 3.1$; $p<0.05$).

Results: Data selection yielded the largest-to-date neuroimaging sample of females with ASD (N=91), along with a sample of males with ASD (N=422) and controls (N males=472, N females=218). Across most R-fMRI metrics, there were significant main effects of diagnosis, sex, and age, along with their significant three-way interaction. A region in the right inferior parietal lobule (IPL) showed consistently across a range of R-fMRI metrics decreases as a function of increasing age in females with ASD compared to males with ASD. The opposite pattern was evident in neurotypicals. This region significantly mapped onto cognitive components related to sensory visceral, inhibitory control and theory of mind functions. Across all results sex differences were most pronounced in adults compared to younger ages.

Conclusions: Results of this cross-sectional design indicate that relative to neurotypical males and females, age-related sex differences in ASD occur in IPL consistently across R-fMRI metrics. The pattern in males with ASD resembles that seen in neurotypical females, whereas the pattern in females with ASD resembles that in neurotypical males, suggesting that age-related factors come into play in models of ‘gender-incoherence’ of ASD. Future work is warranted to confirm current results in longitudinal samples.

182.048 Using Resting State Functional MRI to Build a Personalized Autism Diagnosis System

O. Dekhil[1]*, H. Hajjdiabe*[2]*, B. Ayinde*[3]*, A. Shalaby*[4]*, A. Switala*[5]*, A. Elshamekh*[6]*, M. Ghazal*[2]*, R. Keynton*[4]*, A. S. El-Baz*[5] *and G. Barnes*[7]*, (1)Bioengineering, university of Louisville, Louisville, KY, (2)Electrical and Computer Engineering, Abu Dhabi University, Abu Dhabi, United Arab Emirates, (3)Electrical and Computer Engineering, University of Louisville, Louisville, KY, (4)Bioengineering, University of Louisville, Louisville, KY, (5)University of Louisville, Louisville, KY, (6)Bioengineering, Univeristy of Louisville, Louisville, KY, (7)University of Louisville School of Medicine, Louisville, KY*

Background:

Autism spectrum disorder (ASD) is a neurodevelopmental disorder affecting approximately 1 in 68 people. Yet, there is no confirmed cause identified for ASD. Studying brain functional connectivity via resting state functional MRI (rs-fMRI) is one of the trending techniques used in understanding ASD.

Objectives: We tested the feasibility of using rs-fMRI data to build a computer-assisted diagnosis (CAD) system for ASD. From the clinical point of view, such a system could be of great value as it helps to predict and understand behavior of autistic individuals from very early, since rs-fMRI may be acquired even from infants. This is an important step towards advancing personalized medicine in autism, which is the ultimate goal of our group’s research efforts in this area.

Methods:

Resting state functional MRI data for 202 subjects were obtained from the National Database for Autism Research (NDAR). These were used to train and test a deep learning-based system to automatically detect rs-fMRI features potentially diagnostic for ASD. Power spectral density of time courses corresponding to the spatial activation areas were raw features input to a stacked autoencoder network. The higher-order representations produced by the network were used to build a classifier based on probabilistic support vector machines.

Results:

Hyperparameter optimization for the stacked autoencoder resulted in the selection of sparseness $\rho = 0.3$, sparse penalty $\beta = 1.0$, and weight regularization $\mu = 10^{-5}$. With these training parameters, classification accuracy was estimated via two-fold cross validation to be 0.856, with sensitivity of 0.984 and specificity of 0.798. Area under the ROC curve was 0.962. Using the ASD prevalence of the general population (1:68), the corresponding positive predictive value (PPV) is 0.44 and negative predictive value (NPV) is 0.998. In a high risk population where an older sibling has ASD, the prevalence is 18.7% (*Pediatrics* 128:e488, 2011), and the corresponding PPV is 0.925 whereas NPV is 0.982.

Conclusions:

This fMRI algorithm may be more informative in high-risk cases than in the general population. In a study of high-risk infants (*Sci Transl Med* 9:eaag2882, 2017), rs-fMRI networks at 6 months of age correctly predicted an ASD diagnosis at 24 months in 9 out of 11 who converted to ASD, and correctly predicted 48 of 48 who did not convert. Few rs-fMRI networks were correlated with social communication and cognitive ability in high-risk infants, while many more were correlated with repetitive behaviors. This suggests a developmental context since striatal and brainstem neural networks tend to mature earlier than cortically based networks. In the older population of the present study, we identified similar regions with altered connectivity previously noted in ASD including the pre-motor, supplementary motor, dorsal lateral, medial prefrontal, and sensorimotor cortex and regions involved in language. Previous rs-fMRI studies have noted that some of these regions, as parts of the Default Mode Network and interhemispheric connectivity networks, have reduced connectivity in ASD (*Front Psychiatry* 7:205, 2017). The data presented suggest the algorithms, especially when combined in a multimodal approach, have the potential to inform a diagnosis of ASD.

49 **182.049** Utilizing Resting-State fMRI to Explore Insula Functional Connectivity in Individuals with and without Autism Spectrum Disorders

*S. M. Francis[1], J. Camchong[1], A. Tseng[1], L. Goelkel-Garcia[2], L. Brickman[3], B. A. Mueller[1], K. O. Lim[1] and **S. Jacob**[1], (1)Department of Psychiatry, University of Minnesota, Minneapolis, MN, (2)Department of Anesthesiology, University of Minnesota, Minneapolis, MN, (3)Rosalind Franklin University of Medicine and Science, Chicago, IL*

Background: Under the theory of embodied simulation put forth by Gallese and colleagues (2005, 2006), impairments in brain regions that integrate internal and external information may lead to deficits in social information processing (SIP). Recent neuroimaging studies report that the insula plays a key role in behavioral aspects that mediate SIP. The insula consists of three cytoarchitectectonically distinct regions: the anterior insula (AI), which participates in emotional salience detection and attentional control; the posterior insula (PI), which is involved in sensorimotor integration, body orientation, environmental monitoring, and response selection; and a transitional dysgranular zone. Autism spectrum disorders (ASD) are commonly characterized by deficits in social interaction and communication. Given these observed social behavioral impairments in ASD and the role played by the insula in SIP, investigating the functionality of this area in ASD is important.
Objectives: To further understand the role of the insula in ASD, we investigated differences in functional connectivity (FC) during the acquisition of resting-state functional magnetic resonance imaging (rs-fMRI) data in male children and adolescents with and without ASD.

Methods: Resting-state FC data was collected in 30 male participants (Age: 10-17 years). Thirteen participants had ASD diagnoses (Age: M=14.6; range 10.2-18) and 17 individuals were typically-developing controls (Age: M=14.4; range: 10-17.5). With seed-based FC measures, we compared resting FC in AI and PI networks between groups. We utilized the Social Communication Questionnaire (SCQ) to assess social functioning.

Results: We found lower FC in the ASD group between AI and superior frontal gyrus (SFG) and thalamus when compared to controls. We also noted hypoconnectivity between PI and inferior parietal lobule (IPL), fusiform gyrus (FG), and lentiform nucleus/putamen in comparison to controls. Conducting a regression analysis using SCQ scores as a continuous variable (without having a distinction between groups), we observed lower SCQ scores were associated with higher FC between: AI and SFG; AI and thalamus; PI and FG; and PI and IPL.

Conclusions: It has been hypothesized that the heterogeneity observed in ASD may be associated with variation in connectivity within and between neural networks. In our investigation, we found hypoconnectivity between the insula and several brain areas (e.g., IPL, FG) in participants with ASD relative to controls. When using SCQ scores from the ASD and control groups to create a continuum, we observed lower scores were associated with higher FC between the insula and some of the same regions. These findings suggest further investigation of the insula's role in SIP across a spectrum of social abilities is needed.

50 **182.050** Visual-Evoked Potential Morphology Differences across Rare Genetic Disorders with Heightened Risk for ASD

***L. Gabard-Durnam**[1], C. E. Mukerji[2], K. J. Varcin[3], J. LeBlanc[4], L. M. Baczewski[5], J. Keller[6], S. Jeste[7] and C. A. Nelson[6], (1)Pediatrics, Harvard Medical School, Boston, MA, (2)Harvard University, Cambridge, MA, (3)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (4)Harvard Medical School, Boston, MA, (5)Education, UCLA Center for Autism Research and Treatment, Los Angeles, CA, (6)Boston Children's Hospital, Boston, MA, (7)University of California, Los Angeles, Los Angeles, CA*

Background: Many rare genetic disorders confer elevated risk for developing Autism Spectrum Disorder (ASD). These disorders provide unique opportunities to evaluate how specific mutations contribute to ASD phenotypes, including altered sensory information processing. However, few studies have directly compared how different genetic mutations disrupt cortical processing of sensory information. Visual-evoked potentials (VEPs), measured with electroencephalography (EEG), provide a noninvasive, translational index of basic sensory processing for comparing visual cortical function across ASD populations, and they could serve as a stratification biomarker across conditions.
Objectives: (1) We compared VEP component morphologies to identify distinct markers of disrupted visual processing across the following disorders: Rett Syndrome, Tuberous Sclerosis Complex (TSC), Phelan-McDermid Syndrome (PMS), FOXG1, CDKL5, and PTEN. (2) Given the challenging nature of processing brief, high-artifact EEG recordings collected in infants and young children, we developed a standardized, automated pipeline optimized for this class of EEG data to improve statistical power and reproducibility of results.

Methods: Data collection is ongoing. Using 128-channel HydroCel Geodesic Sensor nets, pattern-reversal VEPs have been elicited from 37 female Rett participants and 20 age-matched typically developing (TD) children, 17 TSC participants, and 18 age-matched TD infants, 7 PMS participants, 2 FOXG1 participants, 4 CDKL5 participants, and 2 PTEN participants. Analyses below focus on the Rett and TSC participants, although we will present data on all groups at INSAR. Data were manually-inspected for artifact, and subject to automated amplitude-based artifact detection. VEPs were extracted for the Oz electrode. We also introduce and compare processing with the Harvard Automated Processing Pipeline for EEG (HAPPE), freely-available software for fully-automated, standardized processing optimized for developmental EEG data.

Results: The TSC group had significantly more negative N1 amplitudes than the Rett group ($p < 0.005$), but was not significantly different from either TD group ($p > 0.05$). The Rett group also had significantly smaller P1 and N2 component amplitudes compared to the Rett age-matched TD group, the TSC group, and the TSC age-matched TD group (all $p < 0.005$). No latency effects distinguishing either disorder group from the other groups were observed. Post-hoc analysis revealed that the N1 amplitude difference between the Rett and TSC groups was driven by the 9 TSC infants who later received an ASD diagnosis (TSC+ASD), where the TSC+ASD subgroup had significantly more negative N1 components than the Rett group ($p < 0.001$). HAPPE processing of the EEG data outperformed multiple alternative processing strategies, rejecting more artifact while retaining 3 times more trials.

Conclusions: VEP component morphologies are differently affected across the rare genetic disorder groups relative to each other and age-matched TD groups. Preliminary analysis suggests that the youth with ASD differ from each other across the rare genetic disorders as well. Identifying VEP morphology differences that are common across or specific to the distinct mutations may provide translational biomarkers for measuring both the progress of the disorders and future interventions. Therefore, we also introduce HAPPE, an automated pipeline for optimally processing EEG data from developmental populations to facilitate comparisons between studies of these ASD-related disorders.

51 **182.051** ERPs to Congruent Pictures and Sentences in Minimally Verbal Children and Adolescents with ASD

***E. Zane**[1], S. Kresh[2], A. Benasich[3] and V. L. Shafer[4], (1)FACE Lab, Emerson College, FACE Lab, Boston, MA, (2)CUNY Graduate Center, New York, NY, (3)Center for Molecular & Behavioral Neuroscience, Rutgers Univ., Newark, NJ, (4)Speech-Language-Hearing Sciences, CUNY Graduate Center, New York, NY*

Background:

Individuals with Autism Spectrum Disorder (ASD) are believed to struggle with multimodal processing and integration (Brandwein et al., 2013). Such deficits contribute to reduced speech discrimination in ASD (Smith and Bennetto, 2007; Stevenson et al., 2014), since one must rely on simultaneous audio-visual (AV) cues to differentiate sounds in noisy environments (Sumby and Pollack, 1954).

Not only do such lower-order language processes – e.g., phoneme differentiation – require multimodal integration, but so can higher-order processes, like semantic interpretation. When a sentence is spoken in the real world, information represented by the sentence often refers to objects/characters and events present in the visible environment. If an individual cannot simultaneously process AV information, she may struggle to connect linguistic information to her environment, and may miss opportunities for assigning visual referents to linguistic symbols when first acquiring language (Gleitman and Gleitman, 1992; Siskind, 1992).

Objectives:

To use Event Related Potentials (ERPs) to determine how minimally verbal (MV) children and adolescents with ASD process auditory sentences while viewing contextually congruent photographs.

Methods:

We recruited 9 MV children and adolescents with ASD (3 F; Mean age = 7;4) and 9 age-matched neurotypical (NT) peers (2 F; Mean age = 7;4). We also recruited one adolescent with ASD with preserved language/cognitive abilities (VASD) and his NT twin (age=12;9). We showed these 20 participants 224 photographs of animals performing an action (e.g., a frog jumping); 300ms later, a congruent sentence was played (e.g., “the frog jumps”). Photographs remained on-screen while sentences played, and we recorded ERPs from photograph onset.

Averaged activity in posterior electrodes between 400-600ms post-picture onset was used to explore group differences in the Late Posterior Positivity response (LPP), an ERP implicated during the processing of complex pictures (Ferrari et al., 2008). Paired t-tests compared LPPs in individuals with ASD to NT matches.

Results:

In all NT participants, an LPP was elicited, while only one participant with ASD showed such a response ($p < 0.001$). The participant with VASD did not show an LPP.

Conclusions:

NT individuals show large LPP responses to photographs, suggesting that they are attending to the photographs while listening to the sentences. The amplitude and duration of LPPs are similar to posterior positivities elicited by matching AV information in previous studies (Molholm et al., 2004), indicating that the congruency of AV information in our study may have amplified the LPP in NT individuals.

The vast majority of our ASD cohort showed no LPP. Most showed visual obligatories, indicating they initially processed photographs similarly to the NT group; lacking LPPs suggest they stopped attending to photographs once encountering auditory information. Because the child with VASD also showed this pattern, this response might be particular to ASD, rather than dependent on language ability. Future research should test this possibility. Our result accords with speech-perception research showing that individuals with ASD predominantly focus on auditory information when perceiving simultaneous audio-visual cues (Brandwein et al., 2013). Results have far-reaching implications for the on-line processing and acquisition of language meaning in ASD.

52 **182.052** Inter and Intra Hemispheric EEG Coherence in Adolescents with ASD Related to Social Function

A. D. Haendel[1]*, A. Barrington*[2]*, H. K. Schiltz*[3]*, A. J. McVey*[3]*, K. M. Rivera*[3]*, S. Pleiss*[4]*, A. Carson*[5]*, B. Yund*[6] *and A. V. Van Hecke*[7]*, (1)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (2)Biomedical Engineering, Marquette University, Milwaukee, WI, (3)Marquette University, Milwaukee, WI, (4)Great Lakes Neurobehavioral Center, Edina, MN, (5)Pediatrics, Autism Center, Baylor College of Medicine/Texas Children's Hospital, Houston, TX, (6)Psychology, University of Wisconsin Milwaukee, Milwaukee, WI, (7)Psychology, Marquette University, Milwaukee, WI*

Background: While differences in neural connectivity among those with ASD is well-established, there is a paucity of studies that have examined brain connectivity across an intervention for ASD. Electroencephalogram (EEG) is a flexible tool to assess neural differences related to ASD (Coben, Mohammad-Rezazadeh, & Cannon, 2014). People with ASD have been characterized as having relatively greater right-versus-left-frontal hemisphere activity (Burnette et al., 2011; Moncrieff, 2010). Further, at rest, people with autism show functional under-connectivity in anterior-posterior connections (Cherkassy et al, 2006).

Objectives: The primary objective of the current study was to examine EEG coherence in the alpha band and relations to social behavior among adolescents with ASD before and after a social skills intervention.

Methods: Fifty-nine (59) adolescents between the ages of 11-16 years participated in this study. Autism was confirmed with the ADOS and IQ was assessed with the KBIT-2; an IQ of ≥ 70 was necessary for participation. Participants were part of a RCT of the PEERS® intervention, which is a manualized, social skills treatment for youth with ASD. Both before and after intervention, adolescents or caregivers completed the Quality of Socialization Questionnaire (QSQ), Social Responsiveness Scale (SRS) and Test of Adolescent Social Skills Knowledge (TASSK).Electroencephalogram (EEG) was performed in a three-minute eyes-open resting state paradigm. The Magnitude Squared Coherence (MSC) was calculated with MatLab using the Minimum Variance Distortionless Response method (MVDR; Capon, 1969) to examine the relation between two signals. Six coherence measures (frontal, temporal, and parietal regions in each hemisphere respectively) were calculated for each participant at pre- and post-intervention. The alpha band (8-12 Hz) was examined because it is associated with neural activity at rest. After distribution analysis, Spearman rank-order (rho) correlations were performed of EEG coherence and social outcome scores before and after intervention.

Results: At pre-, a positive relation was found between the Temporal Right-Temporal Left coherence and the QSQ Total, (r_s (59) = .36, $p < .05$). At post-, results revealed negative links between the SRS Autistic Mannerisms Subscale and Frontal Left-Frontal Right (r_s (59) = -.39, $p < .01$), Temporal Right-Temporal Left (r_s (59) = -.31, $p < .05$), Parietal Right-Parietal Left (r_s (59) = -.36, $p < .01$), and between QSQ Total and Frontal Right-Parietal Right (r_s (59) = -.32, $p < .05$).

Conclusions: Findings at pre-intervention provide further support for the under-connectivity theory of ASD. Furthermore, results demonstrate additional associations between coherence and social behavior were found at post test. Across intervention, as autism severity symptoms decrease, the neural connectivity between specified brain regions increases. These findings will be examined further by comparing additional participants as well as comparing data to typically developing adolescents as well as a delayed treatment group. Findings of this study have implications for the structure of interventions for ASD across settings as well as gaining an understanding of neural and behavioral plasticity in ASD.

Poster Session
183 - Diagnostic, Behavioral & Intellectual Assessment
11:30 AM - 1:30 PM - Hall Grote Zaal

54 **183.054** A Comparison of Males and Females Presenting for an ASD Evaluation in Young Childhood

S. Richardson[1]*, C. Beacham*[2]*, L. J. Dilly*[1] *and C. Klaiman*[3]*, (1)Marcus Autism Center, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta, and Emory University School of Medicine, Atlanta, GA, (3)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background: The research on gender differences in ASD symptomatology is inconsistent, yet clinicians often perceive differences in presentation for girls and boys. One large scale study with a wide age range represented found weaker observed social communication and interaction skills for females (Frazier et al., 2014), while another found stronger skills for females, at least on certain ADOS-2 modules (Mussey et al., 2017). Other studies suggest fewer repetitive behaviors in females (Frazier et al., 2014; Mandy et al., 2012). Despite the importance of identifying ASD at an early age, prior research has not specifically focused on gender differences in toddlers and how this may be captured on assessment measures.
Objectives: Evaluate gender differences in autism symptomatology in toddlers, assessed by the ADOS-2, and level of developmental functioning, as assessed by the Mullen.

Methods: The sample consists of 178 males and 44 females between the ages of 14-45 months (M = 29.39 months, SD = 6.5 months) referred based on parent concerns and/or provider recommendations who received an ASD diagnosis. Comprehensive ASD diagnostic evaluations consisted of the Mullen Scales of Early Learning (Mullen), Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), parent-report measures (M-CHAT-R, ASQ-3), and parent interviewing.

Results: Preliminary analyses showed no differences in ADOS-2 module used by gender (Module T = 58%, Module 1 = 36%, Module 2 = 7%). There were no significant differences between the four assessed Mullen domains by gender (Visual Reception: Males M = 31.31, SD = 11.36; Females M = 33.82, SD =11.59, Fine Motor: Males M = 28.45, SD =9.77, Females M = 28.59, SD = 10.18, Receptive Language: Males M = 25.06, SD = 10.4; Females M = 26.36, SD = 10.24, Expressive Language: Males M = 25.86, SD = 9.61; Females M = 26.98, SD = 9.53). Additionally, there were no significant differences in ADOS-2 Social Affect, Repetitive Behaviors, or total scores. At the item level, there was only one trend found with females scoring lower on facial expressions directed to others. Follow-up, exploratory analyses found more differences in toddlers with below average to average Mullen expressive language scores (n = 27 males, 8 females). Girls were found to have significantly lower scores on facial expressions directed to others ($t(33)= 3.02$, $p<.005$), quality of social overtures, ($t(26) = 2.13$, $p <.05$), and a trend for lower scores on pretend play ($t(33) = 1.78$, $p = .08$).

Conclusions: Results are generally consistent with previous research conducted with older individuals finding that girls and boys are more similar than dissimilar. Subtle differences were found for individuals without significant delays in expressive language skills, with girls showing a greater range of facial expressions, increased quality of social overtures, and better pretend play skills; however, this should be interpreted with caution as findings need to be replicated in a larger sample. Although findings from this community-referred sample can be generalized to clinical practice, it is possible that more subtle, higher-functioning children were missed in this sample, particularly considering the delays found developmental functioning for this sample.

55 **183.055** A Patient Report Outcome Measure of Sensory Difficulties in Autism Spectrum Disorder

H. Bruining[1]*, D. M. van Andel*[2] *and H. van Stel*[3]*, (1)Brain Centre Rudolf Magnus, Amsterdam, Netherlands, (2)Brain Center Rudolf Magnus, Department of Psychiatry, UMC Utrecht, Utrecht, Netherlands, (3)Julius Center, UMC Utrecht, Utrecht, Netherlands*

Background:
The addition of hyper or hypo reactivity to sensory input as diagnostic criterion in Autism Spectrum Disorder (ASD) calls for a new approach to identify and quantify atypical sensory behavior in daily life. Studies report both over and under responsiveness in children with ASD and similar physiological sensory processing deficits can lead to a variety of behaviors. Currently used instruments cannot capture the wide heterogeneity of these behaviors: the questionnaires are often diagnostic tools, developed from the perspective of the professional and symptom based. Besides, it is acknowledged that current tools and questionnaires for ASD have significant limitations to be used as a patient-oriented outcome measure for intervention research. They have no established cut-off for clinically relevant change, a *minimal important difference*. Considering the recent focus on and rise in novel interventions aimed at treating aberrant sensory processing, the need arises for relevant outcomes from the perspective of patients and/or caregivers themselves that can be used in both clinical and research settings.

Objectives:

To develop and validate a patient-reported outcome measure (PROM) for problems arising from sensory reactivity difficulties in daily life that additionally serves as (relevant) effect measure in intervention studies.

Methods:

This is a mixed-methods study guided by the iterative approach described in the US Food and Drug Administration Guidance for Industry Patient-reported Outcome Measures. Information from 20 parents of patients with different severity of ASD and intellectual functioning was collected. Qualitative thematic data analysis resulted in main themes, pool of items and response options, providing a pilot version of the PROM. Weighting was added to individualize the PROM. ‘Think aloud’-procedures will be used to evaluate and optimize pilot versions and psychometric testing will be carried out to assess validity, reliability and sensitivity to change.

Results:

First results show major discrepancy between items on conventional questionnaires and our reported main themes. We have identified novel and meaningful problem areas, such as fatigue, anger outbursts and attentional problems, which currently used questionnaires have failed to address.

Results of the development of the PROM and preliminary data will be presented.

Conclusions:

By using a novel approach to identify and quantify sensory reactivity deficits in children with ASD in daily life, we will be able to develop a multidimensional and individually tailored PROM. Now we can identify and compare sensory reactivity deficits on both individual and group level for future application as outcome measure for interventions and clinical trials.

56 **183.056** A Promis®-Based Approach to Item Development and Factor Analysis of the Emotion Dysregulation Inventory for Youth with ASD

T. N. Day[1]*, L. Yu*[2]*, M. Siegel*[3]*, S. W. White*[4]*, P. Pilkonis*[2] *and C. A. Mazefsky*[5]*, (1)Florida State University Autism Institute, Tallahassee, FL, (2)University of Pittsburgh School of Medicine, Pittsburgh, PA, (3)Maine Medical Center - Tufts School of Medicine, Westbrook, ME, (4)Psychology, The University of Alabama, Tuscaloosa, AL, (5)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA*

Background: Poor emotion regulation maintains behavioral problems in autism spectrum disorder. Thus, emotional dysregulation is an ideal treatment target. However, measures of this construct are lacking for youth with ASD, and available measures that do exist are reliant on verbal ability. Little is known about the presentation of emotion dysregulation in youth with ASD – especially across the range from nonverbal to fully verbal and intellectual capacity.

Objectives: Using Patient-Reported Outcomes Measurement Information System (PROMIS) guidelines, this presentation will describe the creation of items tapping observable manifestations of poor emotion regulation in youth with ASD, and the dimensionality of emotion dysregulation in ASD. These represent the initial steps in the development of the *Emotion Dysregulation Inventory* (EDI).

Methods: A comprehensive literature search and the development of a conceptual model occurred to derive the item-bank. Candidate items underwent expert review, followed by interviews conducted with caregivers of 19 individuals with ASD who ranged in age, verbal ability, and cognitive functioning. The interviews combined a think-aloud and debriefing methodology; further detail will be provided. The 66 candidate items were evaluated via caregiver report in two samples: (1) Interactive Autism Network (IAN; *n*=1323, ages 6-17) representing the full range of ASD severity and adaptive functioning; and (2) Autism Inpatient Collection (AIC; *n*=432, age 4-20). The AIC is a six-site study of psychiatric inpatients with ADOS-confirmed ASD that includes participants with extreme forms of emotion dysregulation. Exploratory factor analysis (EFA) and confirmatory factor analysis (CFA) were conducted in non-overlapping subsamples (*n*=870 for EFA, 885 for CFA).

Results: Clinicians and researchers with expertise in ASD reviewed candidate items; recommended modifications were incorporated. Parent interviews indicated that items had sufficient coverage of emotional reactivity and regulation and were understandable to parents. Collectively, these steps provided evidence of face validity for the target construct. EFA identified a 2-factor model: (1) Reactivity, characterized by intense, rapidly escalating, sustained, and poorly regulated negative emotional reactions, and (2) Dysphoria, characterized by anhedonia, sadness, and nervousness. The factor structure did not differ for the IAN and AIC samples, despite lower verbal and cognitive ability in AIC compared to IAN. CFA in an independent sample demonstrated adequate to good fit for both factors. An overall total score to subsume the two factors was not supported.

Conclusions: The strategy used to develop the EDI was effective in creating an item bank with sufficient content coverage and ease of understanding. Factor analyses of EDI candidate items supported distinct dimensions of emotion dysregulation in ASD. Consistent with studies in non-ASD samples, the tendency to experience intense negative emotion and difficulty regulating emotion emerged as a single factor (i.e., Reactivity), which was separable from general unease (Dysphoria). Future directions include the downward age extension of the EDI to examine the presentation of emotion dysregulation in younger children.

57 **183.057** Adolescent Autism Traits: Associations with Parental Age and Physiological Functioning

A. Arias[1]*, A. J. McVey*[1]*, H. K. Schiltz*[1]*, A. D. Haendel*[2]*, K. M. Rivera*[1]*, S. Pleiss*[3]*, A. Carson*[4]*, B. Yund*[5] *and A. V. Van Hecke*[6]*, (1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Great Lakes Neurobehavioral Center, Edina, MN, (4)Baylor College of Medicine, Houston, TX, (5)Psychology, University of Wisconsin Milwaukee, Milwaukee, WI, (6)Psychology, Marquette University, Milwaukee, WI*

Background: Both older maternal and paternal age, have been identified as risk factors for having a child with autism (Grether et al., 2009). Little is known regarding the links between parental age and autism severity. Furthermore, atypical cardiac activity has been uncovered among adolescents with ASD (Van Hecke, et al. 2009), suggesting physiological dysregulation (Guy et al., 2014). Thus, autism severity may be associated with physiological arousal and parental age might have implications for both.

Objectives: 1) Explore relations between caregiver-report of autism traits and parental age among a sample of adolescents with ASD. 2) Examine associations between caregiver-report autism traits and physiological arousal measured using heart rate. 3) Determine if HP mediates the link between parental age and caregiver-report of autism traits. Our hypotheses are that positive associations will be uncovered for our first objective, whilst negative associations will be found in our second objective. Finally, HP will mediate the link between parental age and autism traits.

Methods: 167 adolescents with ASD aged 11-16 and their parents/caregivers participated in this study. Participants presented for a RCT of a social skills intervention; data here is from pretest. Descriptive statistics are in Table 1. Caregivers completed a demographic form that asked about maternal and paternal age. Presence of autism was confirmed with the ADOS, IQ was measured with the KBIT-2. All participants had an IQ ≥ 70. Caregivers also completed the Autism Quotient (AQ) and Social Responsiveness Scale (SRS) as measures of autism traits, which were analyzed at a subscale and total score level. Higher scores on these measures indicated greater autism severity. Heart period (HP) data were collected from a sub-sample (*n* = 94).

Results: Negative links were uncovered between maternal age and the AQ Communication (*r*(167) = -.157, *p* = .043) and SRS Cognition subscales (*r*(167) = -.187, *p* = .016). Considering paternal age, negative relations were found for the AQ Communication (*r*(160) = -.192, *p* = .015), SRS Cognition (*r*(160) = -.223, *p* = .005), SRS Autistic Mannerisms subscales (*r*(160) = -.179, *p* = .023), and SRS Total (*r*(160) = -.194, *p* = .014). Associations between HP and the SRS Cognition (*r*(93) = -.206, *p* = .046), Autistic Mannerisms (*r*(93) = -.224, *p* = .030), and Total (*r*(93) = -.315, *p* = .002) were found. No significant mediation was uncovered.

Conclusions: The negative links uncovered between parental age and autism severity suggest that milder symptoms are found in children of older parents. This may indicate that, in addition to established associations with risk for having a child with autism, parental age may also be associated with the severity of autism symptoms. Because older parental age was associated with less severe scores on the SRS, future studies might explore other factors related to parental age (such as parenting style) as these may impact the severity of autism symptoms in their children (Mohammadi & Zarafshan, 2014). Furthermore, a negative link was discovered between autism severity and physiological arousal, thus, more physiological dysregulation seems to be related to greater autism severity.

58 **183.058** ADOS-2 Classification in a Psychiatric Population

C. Colombi[1,2]*, A. M. Fish*[1] *and M. Ghaziuddin*[3]*, (1)Psychiatry, University of Michigan, Ann Arbor, MI, (2)University of Michigan, Ann Arbor, MI, (3)University of Michigan, Ann Arbor, Ann Arbor, MI*

Background: the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), is considered a "gold-standard" instrument for diagnosing autism spectrum disorder (ASD) in adults. Despite good sensitivity and specificity of the ADOS-2 are demonstrated in research and clinical settings with highly trained examiners, little is known about the accuracy of the diagnostic classification with psychiatric populations. Objectives: to evaluate the accuracy of the ADOS-2 diagnostic classification in an acute psychiatric population.

Methods: we evaluated diagnostic classification of the first 36 individuals admitted to the inpatient unit with a possible ASD diagnosis. Reasons for admission included anxiety, depression, conduct disorder, oppositional defiant disorder, self-injurious behavior, and suicidal ideation.

Results: 8 out of a total of 36 individuals with ASD did not meet diagnostic criteria for classification in the ADOS-2. 8 out of a total of 36 individuals with Non Spectrum diagnosis met diagnostic criteria for classification in the ADOS-2. Sensitivity and specificity were both at 77% with 20 individual classified correctly (55%) and 16 individuals classified incorrectly (44%).

Conclusions: results indicate that the ADOS-2 diagnostic classification in patients admitted to a psychiatric unit should be interpreted carefully given the number of individuals classified incorrectly by the instrument.

59 **183.059** Adult Manifestations of Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS): A Combined Epidemiological and Case Register Study.

E. Horwitz[1]*, R. A. Schoevers*[2] *and C. A. Hartman*[3]*, (1)University Psychiatric Clinic, University Medical Center Groningen, Groningen, Netherlands, (2)Psychiatry, University Medical Center Groningen, Groningen, Netherlands, (3)Department of Psychiatry, Interdisciplinary Center Psychopathology and Emotion Regulation (ICPE), University Medical Center Groningen, Groningen, Netherlands*

Background: Autism Spectrum Disorder is a highly heterogeneous disorder which is currently defined on the basis of childhood behavioral repertoire. Limited information is available on features of the autistic phenotype in adults. Knowledge on the outcome for individuals with normal intelligence with milder forms of ASD is scarce.
Objectives: The aim of this study is to describe autistic and comorbid psychopathology in young adults, with a previous clinical diagnosis of PDD-NOS. Based on scores on dimensional and categorical diagnostic measures their profile of ASD and comorbid psychopathology is compared to that of young adults in specialist psychiatric healthcare without an ASD diagnosis.

Methods: Participants from the TRacking Adolescents' Individual Lives Survey (TRAILS-clinical cohort) with a PDD-NOS (n=148) or other (n=250) diagnoses as registered in the Psychiatric Case Register North Netherlands between age 11 and 19 were compared, at age 19, on ASD symptomatology (Autism Diagnostic Observation Schedule (ADOS) module 4, Adult Social Behavior Questionnaire (ASBQ) self- and other-report versions) and comorbid diagnoses (Composite International Diagnostic Interview (CIDI) and ADHD self- and other checklists).

Results: Young adults with an PDD-NOS or Asperger diagnosis in childhood on average scored higher on the ADOS and ASBQ than clinical controls, but the majority (72%) did not exceed the ASD cutoff according to the ADOS. Eighty-one percent of the ASD group compared to 97 % of the clinical controls fell outside the ASD spectrum according to the ADOS Calibrated Severity Scale. Differences between ASD and control groups were larger on ASBQ other-report than on ASBQ self-report. On all subscales of the ASBQ differences between ASD and clinical control groups scores reached statistical significance, apart from self-report on the *violation of social conventions* and *sensory stimulation / motor stereotypies* subscales. Number of comorbid psychiatric disorders according to the CIDI did not differ significantly between the groups. The ASD group was more dependent on mental health care in and psychiatric medication than the clinical comparison group.

Conclusions: A clinical PDD-NOS diagnosis in early adolescence in most cases did not lead to an ASD classification according to ADOS in young adulthood in our sample. Compared to a clinical comparison group, young adults with a previous PDD-NOS diagnosis had on average higher scores on ASD measures, had an equal level of psychiatric comorbidity and were more dependent on mental health care. In adolescence, milder expression of ASD symptomatology may be transitory and might form part of a multidimensional early syndrome with important variation in diagnostic outcome.

60 **183.060** Are Approaches of „Machine Learning" and „Support Vector Machines" Suitable to Improve the ASD Diagnostic Process in Children and Adolescents?

I. Kamp-Becker[1]*, F. Hauck*[2]*, N. Kliewer*[2]*, S. Köhne*[3]*, L. Poustka*[4]*, S. Roepke*[5]*, V. Roessner*[6]*, N. Wolff*[7] *and S. Stroth*[8]*, (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Schutzenstr 49, Germany, (2)Department of Information Systems, Freie Universität Berlin, Berlin, Germany, (3)Berlin School of Mind and Brain, Humboldt University Berlin, Berlin, Germany, (4)Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Goettingen, Goettingen, Germany, (5)Department of Psychiatry, Charite Berlin, Berlin, Germany, (6)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Dresden, Germany, (7)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus Dresden, Dresden, Germany, (8)Philipps University Marburg, Marburg, Germany*

Background: Existing diagnostic instruments do, in fact, identify individuals with ASD accurately, but sometimes fail to differentiate individuals with ASD from those with other psychiatric disorders and complex neuro-behavioral profiles (such as ADHD, emotional and personality disorders and others). For these reasons, the identification of features which discriminate between different but overlapping phenotypes is of great importance. Recently, pattern classification methods based on machine learning algorithms have been used to predict or classify individuals of

different phenotypes.
Objectives: The objective of the talk is to focus on both, machine learning algorithms and support vector machines to classify distinguishing dimensions of the ASD diagnostic process .

Methods: These innovative approaches were applied to the data of 2,568 children, adolescents and adults to identify those items of the applied diagnostic tools which show the best discriminatory quality. All patients underwent the gold standard diagnostic procedures, ASD diagnosis was confirmed in 1,359 individuals. In almost the same amount of patients (N= 1,209) ASD was excluded and a differential diagnosis was found (e.g. ADHD, language disorder). The outlined machine learning methods (Decision Tree) as well as Support Vector Machine analyses were used to develop algorithms that differentiate ASD from other disorders.

Results: For children and adolescents, a reduced number of differentiating items that exhibited good diagnostic accuracy was identified. Sensitivity ranged from 79 – 96%, specificity was found between 63 – 77%.

Conclusions: In sum, for young children accuracy was higher than for older. Social orientation in interaction behavior seems to be a core and specific symptom of ASD differentiating ASD from other disorders with multitude symptom overlap.

61 **183.061** Association between Subclinical Autistic Traits and Cognitive Functions in General Children: Focusing on Sex Differences

M. Dai[1]*, J. Liang*[1]*, L. Lin*[1,2] *and J. Jing*[3]*, (1)Sun Yat-sen University, Guangzhou, China, (2)Peking University Health Science Center, Beijing, China, (3)Maternal and Child Health, Sun Yat-sen University, Guangzhou, China*

Background: Although sex difference in autism spectrum disorders and children with sub-clinical autistic traits has attracted a variety of research; few studies have addressed sex difference in the associations between AT and cognitive functions.
Objectives: This study aimed to: 1) explore the associations of autistic trait with intelligence profiles and executive functions among general children; and 2) examine whether the associations differed by sex.

Methods: Quantitative autistic traits of 429 general children aged 6-9 years from mainland China were measured using Social Responsiveness Scale. Children were divided into low- and high-autistic-trait (HAT and LAT) groups according to the Chinese cut-off score for ASDs screening. Their intelligence profiles and executive functions were assessed with Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV) and Computerized Version of the Wisconsin Card Sorting Test (WCST) respectively. Demographic information was reported by parents. A series of hierarchical linear regression models for each sex separately were performed to examine the associations between autistic trait and cognitive profiles.

Results: Girls were related to a decreased odds ratio of being in the HAT group (OR=0.54, 95% CI: 0.33-0.88). After controlling for demographic covariates, we observed no significant associations between autistic trait and executive functions; children with HAT had significant lower scores than those with LAT in full IQ and three indices of WISC-IV (β ranged -3.74 to -6.02, all $P<0.05$), except for Processing Speed Index. These associations persisted in subgroups stratified by sex, except for Working Memory index. We found no sex-differences in the interrelations of autistic trait and relevant intelligence profiles (all $P>0.05$). However, the associations of HAT with certain intelligence profiles were much more stronger in girls than those found in boys, including full scale IQ (girls: $\beta=-8.61$, SE=2.54, $P<0.001$; boys: $\beta=-4.43$, SE=1.75, $P=0.012$), Verbal Comprehension Index(girls: $\beta=-8.76$, SE=3.06, $P=0.005$; boys: $\beta=-4.81$, SE=2.14, $P=0.025$) and Perceptual Reasoning Index (girls: $\beta=-9.25$, SE=2.49, $P<0.001$; boys: $\beta=-3.44$, SE=1.63, $P=0.036$).

Conclusions: In general population, autistic trait was negatively associated with certain intelligence profiles, both in boys and girls. Additionally, these associations were much stronger in girls than those in boys. These findings further our understanding of sex difference among individuals along the autistic trait continuum and underline that examining sex difference in the social-cognitive domain should not neglect eliminating the confound effects of sex difference in intelligence profiles.

62 **183.062** Comparison of Symptom Profiles in a Minority Sample of Preschool Children Referred for ASD

J. Durocher[1]*, M. N. Hale*[1]*, A. Beaumont*[1]*, M. Parladé*[1]*, S. Cardona*[2]*, G. Victoria*[3] *and E. M. Davis*[3]*, (1)University of Miami, Coral Gables, FL, (2)Psychology, University of Miami, Coral Gables, FL, (3)Mailman Center for Child Development, University of Miami, Miami, FL*

Background:
ASD diagnosis varies according to race/ethnicity; minority children less likely receive a diagnosis, are diagnosed later, and are more likely to be misdiagnosed with or conduct disorder (Mandell et al. 2002; Mandell et al., 2007). Further, findings regarding variability in symptom presentation and developmental profiles across cultural groups are inconsistent. Minority children have been shown to have lower cognitive and language scores, and higher severity of ASD symptoms including unusual eye contact, stereotyped language, echolalia, and nonfunctional routines/rituals (Chaidez et al. 2012; Cuccaro et al., 2005; Harrison et al.,2017; Landa & Garrett-Mayer 2006; Sell et al. 2012). However, other studies have found relatively little difference between White and Hispanic groups on ASD symptoms, cognitive or adaptive functioning (Chaidez et al., 2012).

Objectives: To compare differences in symptom presentation within a minority sample of Hispanic and Black/African American preschool-age children referred for diagnostic evaluations.

Methods: The sample is comprised of 103 children between the ages of 2 and 5 who were evaluated at an University-based specialty diagnostic clinic as part of a services grant for children suspected of having an autism spectrum disorder. Children were referred directly through local Part C and Child Find services based on the following criteria: (1) at risk for ASD based on screening (2) Medicaid eligible or lacking private insurance (3) Head Start or Early Head Start eligible, or (4) zoned for a Title 1 school based on address. IRB approval for retrospective data analyses was obtained. Participants included those children who received diagnoses of ASD (n=83, 80% of initial sample), with a mean age of 45.57 months (SD=10.54) and nonverbal IQ of 72.76 (SD =24.44). The sample consists of 21 females (25%) and 62 males (75%). Ethnicity/race breakdown is as follows: White Non-Hispanic (1.2%), Asian (1.2%, Hispanic (72.3%), Black/African American (25%). Subsequent analyses will be based on Black (n=21) and Hispanic (n=60) subjects only.

Results: Preliminary results suggest that Hispanic children were significantly older at referral (47.88 vs 39.71 months), t=2.75(27.211), p=.011. There were no group differences in nonverbal IQ, receptive or expressive language. Nonverbal IQ scores below 70 were seen in 52% of each sample; however, Black children had higher rates of speech/articulation disorder (57% vs.35%). Black children had higher ADOS total severity scores

(M=7.37, SD=1.832) than Hispanics (M=5.55, SD=1.832), t(77)= -3.14, p=.002. In contrast, Hispanic children were rated as more severe by parents on the ASRS with respect to Atypical Language (M_H=63.38; SD=8.96 vs. M_B=53.67; SD=11.89), t(38)=-2.334, p=.025 and Self-Regulation (M_H=60.84; SD=10.60 vs. M_B=52.68; SD=12.94), t(38)=-2.756, p=.007. Hispanics were rated as more severe on the BASC on the following subscales: aggression (M_H=51.78; SD=10.26 vs. M_B=46.33; SD=9.78), t(79)=2.12, p=.037 and anxiety (M_H=49.62; SD=9.65 vs. M_B=45.95; SD=5.72), t(59.596)=2.08, p=.042.

Conclusions:

Hispanic and Black children were more similar than different on the majority of measures, including cognitive, language and adaptive behavior. However, differences were found with respect to age of referral, clinician ratings of ASD symptom severity, and parent reported symptoms. Implications of these findings for the diagnostic and treatment process will be discussed.

63 **183.063** Denoising Autoencoders for Self-Supervised Clinical Subtyping of Autism Spectrum Disorder

C. H. Chatham[1], *J. F. Hipp*[2], *P. Garces*[3], *S. Holiga*[3], *J. Tillmann*[4], *E. J. Jones*[5], *M. Uljarevic*[6,7], *G. Dumas*[8], *E. Loth*[9], *T. Charman*[10] *and G. Honey*[11], *(1)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development. Roche Innovation Center Basel, Hoffmann La Roche, Basel, Switzerland, (2)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, Basel, Switzerland, (3)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development. Roche Innovation Center Basel, Hoffmann-La Roche, Basel, Switzerland, (4)Institute of Psychiatry Psychology & Neuroscience, London, United Kingdom, (5)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (6)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (7)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (8)Human Genetics and Cognitive Functions Unit, Institut Pasteur, Paris, France, (9)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (10)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (11)F. Hoffman La-Roche Ltd, Basel, Switzerland*

Background: Several measures have been proposed as candidate biomarkers for ASD but their correlations with clinical symptom severity are typically weak. Consequently, these biomarkers may be less prognostic of clinically-meaningful change, and less revealing of specific mechanisms to target for alleviating distress. One potential cause of these weak correlations is small underlying effects. Alternatively, larger correlations could be attenuated by population heterogeneity. For example, if distinct subtypes of ASD have distinct biomarker/clinical severity associations, then effect sizes could be reduced when ASD is treated as a single, unitary disorder. Although much prior work attempts to uncover the sources of heterogeneity in ASD, most techniques make restrictive assumptions about the nature of this heterogeneity. For example, classical clustering methods can uncover categorical differences within a population, but may give misleading results if dimensional differences exist. Conversely, classical factor analytic methods can recover dimensions, but may give misleading results in the presence of latent categories. There is a clear need for more equipotent techniques, where both latent categorical and latent dimensional sources of variation can be uncovered simultaneously in a data-driven manner.

Objectives: The objective of this study was to uncover latent categorical and/or dimensional clinical features of individuals with ASD, and to examine whether these features may disattenuate the correlation between biomarkers and the severity of clinical symptomatology.

Methods: We apply a self-supervised neural network architecture, the denoising autoencoder, to item-level scores from individuals with ASD on the Autism Diagnostic Interview-Revised, Social Responsiveness Scale, and Repetitive Behavior Scale-Revised, as well as v-scale scores from the Vineland-II Adaptive Behavior Scales. Input data was normalized for age and IQ, to increase variance related to atypical clinical symptomatology. Data from the Simons Simplex Collection (SSC; n=2329 in this analysis) was used to optimize the model through internal cross-validation. Generalization was assessed on a large holdout dataset (EU-AIMS LEAP; n=334 in this analysis).

Results: Our machine learning approach showed good cross-validation performance when item-level scores were compressed to 9 latent features. The model showed minimal overfitting when applied to the holdout dataset, EU-AIMS LEAP. Nine dimensions sufficed for reconstructing up to 85% of the variance in item-level scores, and never reconstructed less than 5% of the variance for any IQ- and age-adjusted item. Moreover, 2 subgroups of individuals with ASD could be reliably extracted from these 9 features, with one subgroup showing a statistically-significant pattern of increased severity across multiple domains (social responsiveness, repetitive behavior and sensory interests, inattentiveness symptoms, gastrointestinal symptoms, the presence of non-febrile seizures, and difficulties with sleep) but, notably, not full-scale IQ. Correlations between neuropsychological performance and clinical severity were (as a whole) larger within this highly-affected subgroup.

Conclusions: Modern machine learning techniques enable the extraction of both continuous and categorical differences among individuals with ASD. Failing to account for these sources of heterogeneity may attenuate the correlation of biomarkers and associated neuropsychological tests with measures of clinical severity.

64 **183.064** Detecting and Assessing Preschool Children with Autism Spectrum Disorder Using Child Behavior Checklist.

Y. H. Lin[1] *and C. C. Wu*[2], *(1)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Department of Psychology, Kaohsiung Medical University , Kaohsiung, Taiwan (Province of China)*

Background: Children with autism spectrum disorder (ASD) usually accompanied emotional and behavioral problems. Children with emotional and behavioral problems could result in more impairments on their social and communication, thus make stress on their caregivers.

Objectives: Children Behavior Checklist 1.5-5 (CBCL/1.5-5) is a tool for evaluating emotional and behavioral problems of preschool children and is used to screen ASD children. However, there is no research in Taiwan. In this study, the CBCL/1.5-5 is used to detect and assess preschool children with ASD.

Methods: 328 children under 48 months old, including 130 children with ASD, 135 children with developmental delay (DD), and 63 children with typical development (TD). The CBCL/1.5-5 was completed by the caregivers for measuring emotional and behavioral problems of all children.

Results: ASD group is higher than DD group and TD group on internalizing problems of broadband scales, withdrawn subscale of syndrome scales, and pervasive developmental problems subscales of DSM-direct scale. In addition, ASD group is higher than TD group on both externalizing and total problems of main scales, and emotionally reactive of syndrome scales. All of withdrawn, pervasive developmental problems and internalizing problems are better index for distinguishing children with ASD from children with DD. Using signal detection theory, cut-off scores of each subscales are as below: T-score of 65 in the withdrawn subscale, the sensitivity and specificity were 69% and 68%, respectively; T-score of 69 in the pervasive developmental problems subscale, the sensitivity and specificity were 70% and 64%, respectively; T-score of 62 in the internalizing problems subscale as the cut-off, the specificity were 63% and 60%, respectively. All of withdrawn, pervasive developmental problems, attention problems, internalizing problems and total problems are better index for distinguishing children with ASD from children with TD. Using signal detection theory, cut-off scores of each subscales are as below: T-score of 59 in the withdrawn subscale, the sensitivity and specificity were 87% and 75%, respectively; T-score of 64 in the pervasive developmental problems subscale, the sensitivity and specificity were 82% and 81%, respectively; T-score of 56 in the attention problems subscale, the sensitivity and specificity were 73% and 64%, respectively; T-score of 59 in the internalizing problems subscale, the sensitivity and specificity were 75% and 72%, respectively; T-score of 58 in the total problems subscale, the sensitivity and specificity were 79% and 68%, respectively. The results revealed that using the withdrawn and pervasive developmental problems subscale as a screening index for detecting children with ASD, it showed accepted validity.

Conclusions: Used the CBCL/1.5-5 as a screening tool for children with ASD, the withdrawn and pervasive developmental problems subscale have moderate validity, suggest the two subscales can be screening tool in the clinical setting.

65 **183.065** Development and Construct Validity of a Comprehensive Feeding Assessment for Children with Autism Spectrum Disorders

***K. K. Ausderau**, B. St John and M. O. Al-Heizan, University of Wisconsin-Madison, Madison, WI*

Background: Feeding challenges are estimated to occur in up to 89% of children with autism spectrum disorders (ASD). Restrictive feeding patterns and preferences may lead to nutrient deficient diets, limited participation in family mealtimes, challenging behaviors, and increased caregiver stress during mealtime. Currently, limited assessment tools exist to assess feeding challenges in children with ASD and ones that do are limited in scope and lack validity and reliability evaluation.

Objectives: The Feeding Assessment for Children with Autism was developed to 1) provide a more complete understanding of feeding disorders of children with ASD and 2) confirm validity of the assessment for use in research and clinical settings. The purpose of this study was to determine the construct validity of the Feeding Assessment for Children with Autism and describe association with child and parent characteristics.

Methods: Exploratory methodological research design was used to determine construct validity of the assessment tool. A large national sample (N=406) of caregivers of children (2 to 12 years in age) and reported feeding challenges was recruited through the Interactive Autism Network. Exclusion criteria included primary hearing, visual, or physical impairments, seizure activity in the last 12 months and other conditions known to co-occur with ASD.

The Feeding Assessment for Children with Autism Spectrum Disorders is a 51-question caregiver-report questionnaire developed to characterize feeding challenges in children with ASD. Questionnaire items are believed to be related to four underlying constructs: sensory (n=13), behavior (n=17), health (n=11), and oral motor (n=10) skills. Confirmatory factor analysis, internal consistency, model fit indices, factor loadings, and between-factor correlation matrix were conducted to determine construct validity.

Results: Primary analysis confirmed a four-factor model was appropriate for the questionnaire items with high internal consistency (0.87). Confirmatory model fit indices indicated moderate fit of questionnaire items into the four constructs. Factor loadings for all four theoretical factors were adequate and statistically significant ($p < .001$) with all loadings >.22. All between factor correlations were statistically significant ($p<.02$) with small-medium positive Pearson r correlations. The behavior factor had medium positive correlations with both oral-motor (.45) and sensory factors (.30).

Conclusions: Findings of the study provide preliminary confirmation of the construct validity of the Feeding Assessment for Children with Autism Spectrum Disorders, providing researchers and clinicians with a comprehensive and psychometrically sound assessment tool to address children's unique feeding challenges. Relatively small correlation magnitudes indicate questionnaire items successfully targeted the four unique feeding challenges. The highest between factor correlations were seen between behavior and all other factors, in particular oral motor and sensory. This finding lends support to the hypothesis that mealtime behaviors observed in children with ASD are in response to other challenges these children face including sensory responsiveness, underlying health concerns, and delayed oral motor skills. This tool will allow for more detailed characterization of feeding challenges with this population, and will help optimize individualized and targeted interventions for children with ASD.

66 **183.066** Development of a Video-Based Coding Tool: Autism Behavioural Change Observational Measure (ABCOM) to Monitor Response to Intervention in School-Age Children with Autism

*M. Custo Blanch[1], M. Sharda[1], R. Ferdinand-Peterkin[2], M. Tan[3], K. L. Hyde[1] and **A. Nadig**[4], (1)International Laboratory of Brain, Music and Sound Research (BRAMS), University of Montreal, Montreal, QC, Canada, (2)BRAMS, University of Montreal, Montreal, QC, Canada, (3)Abaton Integrative Medicine, Oakville, ON, Canada, (4)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada*

Background:
Evaluating outcomes effectively is a significant challenge for intervention research in Autism Spectrum Disorder (ASD). Although many tools exist for monitoring response to intervention in toddlers, few tools exist for the school-age population (Cunningham, 2012). Commonly used measures such as the ADOS were designed for diagnostic purposes, are expensive and require highly-specialized training. The Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al, 2016) was specifically developed to measure changes in social-communication in ASD but is limited to early intervention and depends on caregiver-child interactions during the ADOS. To date, there is no treatment-response tool for school-age children that has applicability across multiple intervention settings, allows for reliable description of functional skills across several clinically-relevant domains, and has the potential to be sensitive to changes in social-communication.

Objectives: The purpose of this study was to develop a flexible video observation-based behaviour coding instrument that may be used in multiple settings (e.g., therapist-child or educator-child play or therapy sessions) for school-age children with ASD to measure response to treatment. Crucially, the tool is designed to evaluate behaviors within a therapy session itself, and therefore does not require the administration of a separate assessment.

Methods: We developed a 27-item questionnaire called the Autism Behavioural Change Observational Measure (ABCOM) to monitor autism-relevant outcomes in school-age children with ASD. The ABCOM (Figure1) is designed to be used in naturalistic settings involving one-on-one interactions with an interventionist/educator. The items are categorized under 6 domains (Table1) which are rated on a likert-scale of 0(never/rarely applies) to 3(almost always applies) based on frequency of behaviours. We used 45-minute video-recordings from a completed randomized control trial (RCT: ISRCTN26821793) comparing music and non-music intervention in 6-12 year-old children with ASD, to develop and test the tool. Two experienced raters were trained using a standardized procedure (lasting 15 hours) using 3 example videos and a written manual to achieve acceptable levels of inter-rater reliability (measured using Intraclass Correlation Coefficient, ICC). 9 videos were coded by both raters till they met intended coding targets. 10 test videos were coded by each rater to measure inter-rater reliability for subsequent independent coding of videos to evaluate treatment-related change in each intervention group.

Results: After initial training and coding of 9 videos, both raters reached an ICC=0.92, p=.001. On the subsequent 10 test videos, raters had an ICC=0.95 (p<.001). Domain-wise ICC and internal consistency values (measured using Cronbach's alpha) are presented in Table1, suggesting high reliability and internal consistency for initiation of communication, shared social interaction and challenging behaviour domains, and acceptable levels of reliability for other domains.

Conclusions: The ABCOM has moderately high inter-rater reliability and consistency and maybe applied in multiple intervention settings to measure autism-related outcomes such as shared social interaction, initiation of communication and occurrence of challenging behaviours in school-age children. Though the ABCOM requires some training of coders, it removes the burden of administering a separate outcome assessment. In ongoing work we are applying this tool to measure the outcomes of the full music vs. non-music RCT.

67 **183.067** Development of the Observation Schedule for Children with Autism Spectrum Disorders– Anxiety and Behaviour (OSCA-AB): A New Measure of Parent and Child Behaviour for Use with Children with ASD

M. Palmer[1], *J. Tarver*[2], *J. Paris Perez*[1], *S. Scott*[1], *V. Slonims*[3], *E. Simonoff*[1], *A. Pickles*[4], *D. Hay*[5] *and T. Charman*[6], *(1)King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (2)University of Birmingham, Birmingham, United Kingdom, (3)Guy's & St Thomas' NHS Foundation Trust (Evelina Children's Hospital), London, United Kingdom, (4)Biostatistics and Health Informatics, King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (5)Psychology, Cardiff University, Cardiff, United Kingdom, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background: Most young children diagnosed with Autism Spectrum Disorders (ASD) display concerning and potentially problematic behaviours and emotions. Emerging evidence suggests that parent training interventions may reduce these difficulties in young children with ASD (Postorino et al., 2017). Trials of parent training frequently use parent-report measures as their primary outcome; however, as parents are the recipients of the intervention they are not blind to treatment status, which may lead to bias is estimating treatment effects (Sonuga-Barke et al., 2013). Objectives: We aimed to develop an objective outcome measure to allow blinded evaluations of interventions for parents of young children with ASD.

Methods: The Observation Schedule for Children with Autism Spectrum Disorders – Anxiety and Behaviour (OSCA-AB) is a measure of parent and child behaviour for use with children with ASD. It draws on existing well-validated observational measures of parent-child interaction. A range of researcher-led and parent-led tasks are completed. Tasks were modified to simulate everyday challenges that children with ASD may face and find difficult. They aim to elicit concerning behaviour and emotions by tapping into uncertainty and novelty, transition, turn taking, sensory processing and compliance. Observed frequencies of parent behaviour (positive and negative comments, clear commands, physical handling, scaffolding) and concerning child behaviours (non-compliance, destructive behaviour, aggression to self and others, avoidance) are coded. In addition, global codes are scored on a Likert scale. Intraclass correlation coefficients (ICCs) were used to establish inter-rater reliability (IRR) using a two way mixed effects model. A more modest ICC of >.60 was selected given that the measure is in development. Pearson correlation coefficients were calculated to investigate the associations between OSCA-AB scores and parent-reports of parent (Parenting Scale - PS) and child behaviour (Aberrant Behaviour Checklist - ABC, Home Situations Questionnaire-ASD - HSQ-ASD).

Results: To date, the OSCA-AB shows adequate IRR for scores on most child variables (ICCs >.60 for 10/15, *Mdn*=.69; *n*=18) and some parent variables (ICCs >.60 for 4/10, *Mdn*=.57). High correlations between the OSCA-AB scores and other validated measures of child behaviour are also evident (*r*=.64 and .61 for the ABC-Hyperactivity subscale and the HSQ-ASD, respectively). However, correlations between observed parent behaviours and parent-reports of their own parenting on the PS are low (*r*=.01-.07). On average, a total of 26 concerning child behaviours are displayed within the 23 minute observation. By May 2018 data from 50 families will be presented following further refinement of the measure and exploration of sensitivity to change over the course of the intervention.

Conclusions: Preliminary results indicate that the OSCA-AB may be a useful objective measure for eliciting concerning behaviour and emotions and parent-child interaction in ASD. Refinement is required to increase IRR for some child and parent variables. Further research is needed to establish whether the OSCA-AB will be a valid measure of parent and child behaviour among samples of young children with ASD and is sensitive to change following intervention.

68 **183.068** Direct in-Person Assessments Add Value When Discerning Autism Spectrum Disorder in SMC1A Variants.

P. A. Mulder[1], *S. A. Huisman*[2], *A. A. Landlust*[1], *R. C. Hennekam*[2], *I. D. van Balkom*[1] *and S. Piening*[1], *(1)Autism Team Northern Netherlands, Jonx (Lentis), Groningen, Netherlands, (2)Department of Paediatrics, Amsterdam Medical Centre, University of Amsterdam, Amsterdam, Netherlands*

Background:
The neurodevelopmental phenotype in individuals with SMC1A variants includes intellectual disability (ID), autism spectrum disorder (ASD) and self-injurious behavior (SIB). A reciprocal interaction exists between neurodevelopmental characteristics, physical phenotype and environment. Differentiating ASD from (profound to severe) ID can be difficult. Individuals with a (severe) ID may meet diagnostic criteria for ASD based on proxy-administered questionnaires, while clinical assessment of their daily functioning may not confirm ASD. This discrepancy can often be explained by the abilities matching their developmental age, which questionnaires do not take into account.

Objectives:

To explore the added value of direct in-person assessments in individuals with SMC1A variants in order to discern ASD from ID and improve our understanding of the neurodevelopmental phenotype.

Methods:

We collected data from behavioral questionnaires in 31 participants (21 international and 11 Dutch) with a SMC1A variant. After informed consent from parents, three authors (PAM, AL, SP) performed interviews and direct in-person neurodevelopmental assessments in a Dutch sample of eight participants. Assessment battery included Autism Diagnostic Observation Schedule - 2 (ADOS-2), Autism Questionnaire (AQ), Bayley III, Wechsler Intelligence Scale (WPPSI-III and WAIS-IV)), Vineland-2, and Short Sensory Profile (SSP)).

Results:

Based on the Social Communication Questionnaire (SCQ) 18/24 participants scored within the clinical cut-off for ASD. For the Dutch group, all eight scored within the clinical range for ASD on the SCQ. Four out of eight participants met ASD criteria based on assessment with the ADOS-2. After careful analysis, two authors (PAM, AAL) agreed that only two of these four participants were impaired by ASD in daily functioning when considering their developmental level (profound and moderate ID). Three of eight participants had a profound ID, 1/8 severe, 1/8 moderate and 2/8 mild and 1/8 scored borderline to normal functioning. Deficits in adaptive abilities were not in line with cognitive abilities (e.g. communication skills were poorer than expected based on developmental level).

Severe difficulties in sensory information processing were present in most participants, more processing time was needed, and shifting between tasks was delayed. Repetitive and restricted behavioural patterns were common.

Conclusions:

From these direct assessments, a clearer picture of neurodevelopmental functioning of individuals with SMC1A variants has emerged. Autism may be assumed in a larger population based on questionnaires, but is less frequently diagnosed after direct in-person assessment and considering behavior in light of developmental level. Direct in-person assessment provides valuable and specific information relevant to understanding the neurodevelopmental phenotype in individuals with SMC1A variants.

69 **183.069** Discontinuities in Autism Spectrum Disorder Traits Among Children with Intellectual Disability

R. Srinivasan[1]*, M. Erwood*[2]*, J. Wolstencroft*[3]*, D. H. Skuse*[4] *and I. D. Imagine*[2]*, (1)UCL GOS ICH, London, United Kingdom of Great Britain and Northern Ireland, (2)UCL GOS Institute of Child Health, London, United Kingdom, (3)UCL GOS ICH, London, United Kingdom, (4)Behavioural and Brain Sciences Unit, Population Policy and Practice Programme, UCL Great Ormond Street Institute of Child Health, University College London, London, United Kingdom*

Background:

Intellectual disability (ID) is characterised by significant limitations in cognitive functioning and adaptive behaviour, and is often associated with behavioural and mental health problems at all life stages. IMAGINE ID is a national UK study of up to 10,000 children with ID of known genetic origin that aims to identify genotype-phenotype risk. Whilst ID in general is strongly associated with ASD traits, the distribution of those traits in relation to genetic aetiology is not known.

Objectives:

Our focus is on children with ID due to pathogenic Copy Number Variants (CNV) or Single Nucleotide Variants (SNV), ascertained by NHS Regional Genetics Centres. By means of online/in-person phenotyping, we aimed to assess the prevalence and severity of ASD traits.

Methods:

1027 participants with ID have been phenotyped to date (mean age 9.1 years; SD=3.8, range 4-18 years). Genetic aetiology was established: i) by microarray analyses (NHS accredited laboratories, with array resolutions typically 100kb); ii) aetiological SNV identified from the UK Deciphering Developmental Disorders survey. Phenotyping was by standardized caregiver psychiatric interview, using the Development and Wellbeing Assessment (DAWBA), which has been validated against ADI/ADOS criteria. Ratings of ASD symptoms were made by experienced clinicians, with high reliability. DAWBA ASD symptom counts were used to generate a continuous severity score. A separate Social Aptitude Scale measured aspects of children's social skills independent of DSM-5 autistic symptomatology.

Results:

42.2% of participants had no significant ASD symptoms, 32.8% of participants met clinical criteria for a diagnosis of ASD, and 25.0% had sub-clinical ASD traits, as measured by a clinical evaluation from interview (DAWBA) material. The ASD group was 63.5% male, the ASD traits group was 52.5% male and the non-ASD group was 46.1% male. There were no significant differences in age, estimated mental age or language age between children with and without clinically identified ASD. When continuous scores were plotted for each subgroup, a normal distribution (confirmed by Shapiro-Wilks analysis) was found for each clinically-defined group. Standardized scores were significantly different ($P<0.0001$) from one another (ASD clinical: 0.76 (95% CI 0.69 to 0.83), ASD traits: 0.18 (95% CI 0.11 to 0.25), no ASD traits: -0.69 (95% CI -0.77 to -0.62). Social Aptitude Scale (SAS) standardized scores were substantially less discrepant from one another, but the mean SAS score was approximately 2SD below national UK norms.

Conclusions:

IMAGINE ID is the first study systematically to evaluate the prevalence of ASD in a national cohort of children with ID of known genetic origin. Our findings indicate that ID arising from CNV/SNV is strongly associated with markedly impaired social aptitude, independent of whether there coexisted significant ASD traits. This approach has the potential to serve as a new way of examining the heterogeneity within different genetic disorders presenting with the same clinical phenotype. The genotypes in this cohort are currently under investigation.

70 **183.070** DSM-5 Criteria and Diagnoses in Adulthood: Are There "Strong and Stable" Features?

S. J. Carrington[1]*, S. L. Barrett*[2]*, U. Sivagamasundari*[3]*, C. Fretwell*[4]*, J. Hall*[5]*, I. Noens*[6,7]*, J. Maljaars*[7,8]*, R. Kent*[9] *and S. R. Leekam*[10]*, (1)Psychology, School of Life and Health Sciences, Aston University, Birmingham, United Kingdom, (2)Wales Autism Research Centre, Cardiff University, Cardiff, United Kingdom, (3)Aneurin Bevan University Health Board, Cwmbran, United Kingdom, (4)Aneurin Bevan University Health Board, Caerleon, United Kingdom, (5)Neurosciences & Mental Health Research Institute, Cardiff University, Cardiff, United Kingdom, (6)Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium, (7)Leuven Autism Research (LAuRes), KU Leuven, Leuven, Belgium, (8)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (9)Institute of Psychiatry, Psychology and Neuroscience, Kings College London, London, United Kingdom of Great Britain and Northern Ireland, (10)School of Psychology, Cardiff University, Cardiff, NSW, United Kingdom*

Background: Autism spectrum disorder (ASD) is a lifelong condition, with some individuals not being diagnosed until adulthood. Individuals seeking diagnosis as adults, however, may present with a different profile compared to children. Previous research examining the stability of ASD behaviours over time has revealed inconsistent findings: while all symptoms tend to decrease over time (e.g. Seltzer et al., 2003), some findings indicate that social and communication difficulties reduce more than repetitive behaviours (e.g. Fecteau et al., 2003) while others find the opposite (e.g. Shattuck et al., 2007). It is, therefore, important to identify which behavioural features are the most robust and stable over time and likely to be potential diagnostic markers in adults.

Objectives: To identify robust features of autism in adults based on DSM-5 criteria.

Methods: Participants were 80 adults with clinically diagnosed ASD (mean age=33.94 years; 52 male, 28 female). The majority (53) were recruited as consecutive referrals from an adult specialist ASD national health clinic, while 27 adults with a known diagnosis of ASD were recruited through university recruitment registers. All adults had an IQ over 70. The Diagnostic Interview for Social and Communication Disorders-Abbreviated (DISCO-Abbreviated; Carrington, Kent, et al., 2014), was carried out independently by researchers. The DISCO-Abbreviated includes published items designed to fit the DSM-5 criteria for ASD, based on a child sample (Carrington, Kent et al., 2014). Frequencies of items and sub-domains endorsed by the adult sample were compared with the original, published sample.

Results: The overall profile of behaviour in adults, indicated by the mean number of behaviours exhibited in the subdomains of the DSM-5 criteria, was similar to previously published data in children; items relating to difficulties with social relationships were endorsed the most frequently, followed by deficits in socio-emotional reciprocity, suggesting that these difficulties in social interactions endure in adulthood. Deficits in non-verbal communication were relatively infrequently endorsed in adults. For the restricted and repetitive behaviours subdomains, the least frequently endorsed behaviours in adults were those related to hypo- and hyper-reactivity to sensory input. The subdomain in which the adult and child profile was most similar measured insistence on sameness. There were no gender differences.

The frequency of individual items endorsed in adults was generally lower than in children. Nevertheless, there were several items with high frequencies in adults. Strong social-communication behaviours included awareness of others' feelings (85%) and sharing of interests (76.3%), which were also highly frequent in children (88.9% and 88.9% respectively). The strongest behaviour for adults in domain B was a limited pattern of self-chosen activities, endorsed by 89% of adults and 97.2% of children. Importantly, those items identified as being most frequent in adults also remained stable over time.

Conclusions: Individuals diagnosed with ASD in adulthood showed a similar profile of behaviours to the published sample of children. Nevertheless, the reduced frequency of behaviours related to non-verbal communication suggest that these behaviours may be less central to diagnosis in adulthood than childhood. Moreover, several items were identified that may be strong and stable diagnostic markers for adults.

71 **183.071** Dyadic Physiological Linkage As a New Measure of Social Reciprocity in ASD

D. Swain[1], *R. S. Factor*[1], *J. Waldron*[2], *Y. Zhou*[3], *M. A. Bell*[4], *A. Scarpa*[5] *and A. Ross*[4], *(1)Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)Psychology, Kaiser Permanente, Blacksburg, VA, (3)Economics, Virginia Tech, Blacksburg, VA, (4)Psychology, Virginia Tech, Blacksburg, VA, (5)Virginia Polytechnic Institute & State University, Blacksburg, VA*

Background: Although early intervention is preferable, little is known about interventions to support the growing population of adults with Autism Spectrum Disorder (ASD) (Mandell,2013; Warren et al.,2011). One core ASD impairment area involves social reciprocity. Because of the impact of social reciprocity impairments, further research on objective measures of social reciprocity can clarify its role in ASD and provide novel ways to assess response to treatment of social impairments.

Objectives: To address these issues, we examined physiological linkage (PL) as a form of social reciprocity. PL refers to coordinated physiological responses between one or more partners in a social interaction. PL is couched in several important constructs in psychology, such as affect matching, mirroring, perspective-taking, and joint attention. As such, we propose that PL encompasses the broader underlying construct of social reciprocity, and thus provides a unique, objective, and quantifiable measure that can be used to further our understanding of social competence in both typical and atypical development in naturalistic interaction contexts.

Methods: In the current study, twenty-six typically developing (TD) dyads and three ASD/TD dyads participated in a social task where each person discussed happy or sad events while the other listened and the cardiac inter-beat interval for each person was monitored. The second-to-second change in the logarithm of the IBI was calculated for each person in each dyad and a bivariate time-series model was specified and estimated, allowing for subject-specific intercepts and gender-specific dynamic lag structures.

Results: In general, for the TD dyads, the findings showed a small but highly significant linkage effect ($p<0.00005$) for both male and female dyads. The effect was stronger for female dyads, however, and persisted to a lag of 4 seconds. For males, the effect was weaker and only significant at a lag of 1 second. For the ASD/TD mixed dyads (2 female and 1 male), the results showed no significant linkage effects for either the ASD or TD subject, and the effect sizes for the results were small. In particular, the null hypothesis of no linkage effect on the ASD person could be rejected only with $p>0.184$ and 0.624 (for the females and the male, respectively); the analogous rejection p-values were 0.332 and 0.624 for the TD person. That is, the ASD person's log IBI did not appear to vary in response to the TD person's log IBI, and vice versa; and the TD person's log IBI did not appear to vary in response to the ASD person's log IBI either.

Conclusions: This study helps to elucidate that TD dyads may have a linkage effect, while ASD/TD dyads do not exhibit the same linkage. While the number of dyads analyzed is small, this preliminary study is one of the first to demonstrate differences in how individuals with and without ASD engage in social reciprocity through PL.

72 **183.072** Evaluation and Norms of the German Version of the Aberrant Behavior Checklist for Children and Adolescents

L. Vllasaliu, *S. Bode, I. S. Kästel, C. E. Köpp, M. Luh, C. M. Freitag and H. Cholemkery, Autism Research and Intervention Center of Excellence Frankfurt, University Hospital Frankfurt, Frankfurt am Main, Germany*

Background:

The aberrant behavior checklist (ABC) was originally developed to measure therapy success in people with mental retardation [1]. Today it is a well-established and worldwide used measure in effectiveness research especially for medication studies. Its validity and reliability has been replicated in different studies which could show its suitability for different age groups and disorders e.g. autism spectrum disorders [e.g. 2,3,4]. It is so widely used that most reviews trying to aggregate autism research can only base their meta-analyses on this questionnaire. Nevertheless the validation is not sufficiently done for every translation. The German version of the ABC has only been validated for adults with mental retardation so far [5] but not for children and adolescents with autism spectrum disorders where it is also widely used and necessary to ensure international comparability of therapy outcomes.

Objectives:

The aim of the present study is to (1) validate the German ABC in children and adolescents with autism spectrum disorder including the factor structure of the subscales, (2) examine its reliability and (3) develop norms.

Methods:

1003 parents of children aged between 4 and 17 years (M: 11.11, SD: 4.09, ♂: 569) were recruited at the Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy of the University Hospital in Frankfurt and filled in the questionnaires. Four different samples were thereby assessed: autism spectrum disorder (n = 225), healthy controls (n = 470), mentally disabled children (n = 128) and a clinical subsample with other mental disorders (n = 180). We examined the validity and reliability of the ABC under consideration of age and gender and developed German norms for this age group. A confirmatory factor analysis was used to confirm the factor structure.

Results:

Item selectivity and Cronbach's alpha were excellent, with the alpha if one of the items is deleted ranging between .963 and .969. The original factor structure of the ABC could be replicated. The retest reliability showed a value of *r* = 0.824 for all items and ranged from 0.796 to 0.864 in case of the five different subscales. The interrater reliability between mother and father ratings was ICC = 0.791 (CI: 0.44-0.92).

Conclusions:

Overall the psychometric properties of the German ABC for children and adolescents could be considered as good to excellent and the factor structure could be replicated. Considering this good results the German ABC can be recommended as a measure of therapy success. This is an important contribution to the international comparability of effectiveness research.

73 **183.073** Examining Symptomatology in ASD in Bilingually Exposed Children

*E. Fornaris[1,2], H. Poore[1,3] and **S. Hoffenberg**[4], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Emory University, Atlanta, GA, (4)Marcus Autism Center, Atlanta, GA*

Background: Although bilingualism and autism spectrum disorder (ASD) is a newer area of research, several studies have shown that introducing a second language to a child with ASD does not affect overall development. When comparing language development in monolingual versus bilingual children with ASD, researchers have found no significant differences in vocabulary, language comprehension, word production, or reading and writing (Uljarevic, Katsos, Hudry, & Gibson, 2016; Reetzke et al, 2015). Preliminary findings have suggested that bilingualism may provide advantages for children with ASD. Valicenti-McDermott and colleagues (2012) utilized primarily parent report on the *Childhood Autism Rating Scale* to examine ASD symptomatology, as well as developmental assessment scores on the *Bayley Scales of Infant Development.* They found that bilingually exposed toddlers with ASD engaged in more gesturing, cooing, and pretend play than monolingual peers with ASD; although studies have not examined these differences in toddlers using the *Autism Diagnostic Observation Schedule, Second Edition (ADOS-2).*
Objectives: The goal of this study is to determine whether differences exist between monolingually and bilingually exposed toddlers with ASD on symptomatology in the areas of language, gestures, play skills, and restricted/repetitive behaviors.

Methods: Participants were 51 toddlers diagnosed with ASD, ranging in age from 19 to 31 months (M=25.1 months, SD=3.8). 18 toddlers were classified as bilingually exposed and 33 as monolingually exposed. Monolingual families spoke English and bilingual families spoke English and another language (83.3% Spanish). The overall sample was 80% male; and 80% of participants were classified as low socio-economic status. 73% identified their ethnicity as non-Hispanic/Latino. Toddlers participated in the *ADOS-2,* Toddler Module and *Mullen Scales of Early Learning* assessments. Developmental assessment t-scores and *ADOS-2* codes for gestures (codes A7, A8), language (codes A1, A1a, A2), play (codes C1, C2, C3), and restricted/repetitive behaviors (codes D1, D2, D3, D5) were compared across bilingually and monolingually exposed children using one-way analysis of variance.

Results: There were no significant differences between monolingual and bilingually exposed children on demographic variables (i.e. age, gender, or SES), nor on developmental assessment scores in visual reception, fine motor, receptive language, or expressive language. There were also no significant differences in language, gestures, or restricted/repetitive behaviors on *ADOS-2* codes. Bilingually exposed toddlers demonstrated significantly greater play skills on the *ADOS-2* than their monolingual peers with ASD (F(1, 49)=3.97, p=.05, d=.58).

Conclusions: In this sample, bilingually exposed toddlers' language skills were not significantly different from their monolingual peers with ASD. This result supports previous findings that exposure to two languages does not exacerbate language delays in children with ASD. In this sample, however, bilingually exposed toddlers had stronger play skills than monolingual peers, consistent with the prior finding that bilingual exposure may confer benefit to children with ASD. This study did not replicate the previous finding that bilingually exposed children with ASD had relatively greater vocalizations or gestures. Given the global prevalence of bilingualism, understanding ASD in bilingual children is vital. Future work should utilize a larger sample size and further examine other possible differences in ASD symptomatology and overall development.

74 **183.074** Examining the Experience of Adults Receiving an Autism Spectrum Diagnosis and Their Later Well-Being.

__R. A. Charlton__[1], F. Happé[2] and P. Abbott[3], (1)Psychology, Goldsmiths University of London, London, United Kingdom, (2)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Autism Diagnostic Research Centre, Southampton, United Kingdom

Background: Relatively little is known about autism spectrum disorder (ASD) across adulthood, or the impact of receiving a diagnosis as an adult. High rates of mood disorders have been reported among autistic adults, and individuals report poor well-being and sleep quality.
Objectives: To follow-up adults who had received an ASD diagnosis to examine whether receiving the diagnosis had been positive and to explore factors associated with well-being.

Methods: Individuals diagnosed with ASD as adults were invited to participate. Of the adults who had consented to be contacted, 44 completed

the study. Individuals responded between 4-80 months (mean=32 months) after receiving an ASD diagnosis.
Individuals completed questionnaires about receiving a diagnosis, autism traits (Autism Quotient, AQ), quality of life (World Health Organization Quality of Life scale, WHOQoL), mental well-being (Warwick-Edinburgh Mental Well-being Scale, WEMWBS) and sleep quality (Pittsburgh Sleep Quality Index, PSQI).
Forty age and sex matched non-autistic neurotypical adults (NA) were recruited from the community as a comparison group. NA completed the same measures; the questions about diagnosis and the AQ were omitted.

Results: *Impact of receiving a diagnosis.* ASD adults were asked about the impact of receiving a diagnosis generally, on their own self-understanding, and on the understanding of others. Individuals were asked if they were aware of support they could access and whether this was what they had expected. Overall individuals felt that receiving a diagnosis had been a positive experience with 72.1% endorsing that it had generally made things better. In terms of post-diagnosis support, overall responses were negative. Most individuals (72.7%) were not clear what (if any) support they could access and 58.5% were not receiving the post-diagnosis support they had expected. See Table 1.

ASD traits and well-being. AQ scores correlated significantly and negatively with WHOQoL subscales (Physical, Psychological, Social, Environmental) and the WEMWBS, indicating poorer well-being with increasing self-report autistic traits. Poorer sleep quality was associated with higher self-report ASD traits, but this did not reach significance. Highly significant associations were observed between sleep quality and all WHOQoL subscales and the WEMWBS.

Group Differences, ASD-NA. The ASD group reported significantly poorer quality of life on all WHOQoL subscales, and on the WEMWBS. Individuals with ASD reported significantly poorer sleep quality than NA.

Conclusions: For most adults receiving an ASD diagnosis, the effect was generally positive, however post-diagnosis support and access to services was not satisfactory. ASD traits were strongly associated with poorer quality of life, mental well-being and sleep quality. Poor sleep quality was strongly associated with poorer quality of life and mental well-being; however the causal directions of these associations are unclear and require further study. Findings suggest that despite growing awareness that autistic adults may be at risk for poor quality of life and mental well-being compared to NA, a gap between awareness and intervention remains. Better monitoring of autistic adults to provide treatment (should poor mental well-being reach clinically significant levels) is required, as is the development of ASD specific interventions.

75 **183.075** Examining the Links between Restricted Interests/Repetitive Behaviors, Respiratory Sinus Arrhythmia, and Anxiety: Do Repetitive Behaviors Mediate the Relation between Rsa and Anxiety?

A. J. McVey[1]*, H. K. Schiltz*[1]*, A. D. Haendel*[2]*, S. Pleiss*[3]*, A. Carson*[4]*, K. M. Rivera*[1]*, B. Yund*[5]*, E. Vogt*[6] *and A. V. Van Hecke*[6]*, (1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Great Lakes Neurobehavioral Center, Edina, MN, (4)Pediatrics, Autism Center, Baylor College of Medicine/Texas Children's Hospital, Houston, TX, (5)Psychology, University of Wisconsin Milwaukee, Milwaukee, WI, (6)Psychology, Marquette University, Milwaukee, WI*

Background: Recent research points to a relation between restricted interests/repetitive behaviors (RRBs) and respiratory sinus arrhythmia (RSA) in ASD (Condy, Scarpa, & Friedman, 2017; Matsushima et al., 2016). Specifically, findings demonstrate a negative link between RSA and ASD symptomology, that is, greater physiological dysregulation (lower RSA) is associated with greater autism severity. Co-occurring anxiety has also been related to both poorer vagal control (Hollocks, Howlin, Papadopoulos, Khondoker, & Simonoff, 2014) and more RRBs (Spiker, Lin, Van Dyke, & Wood, 2012) among samples of youth with ASD.
Objectives: The purpose of this study was to examine the relations between RRBs, RSA, and anxiety and test the mediating role of RRBs in the association between RSA and anxiety among a sample of adolescents with ASD. It was hypothesized that RSA would be negatively associated with RRBs, both RRBs and RSA would be positively related to anxiety, and that RRBs would mediate the association between RSA and anxiety.

Methods: One-hundred fifteen adolescents with ASD participated in this study. Participants presented for a RCT of a social skills intervention; data presented here were from pretest. Presence of ASD was confirmed using the ASDOS-G and IQ above 70 was confirmed with the KBIT-2. Parents or caregivers completed the Social Responsiveness Scale (only the Autistic Mannerisms subscale was used here as a measure of RRBs; SRS-AM) and the Social Anxiety Scale for Adolescents (SAS). Adolescents completed a three-minute eyes-open resting state paradigm during which heart rate data was collected.

Results: A Process mediation model was used to test the mediating role of RRBs (SRS-AM) in the relation between RSA and anxiety. A negative relation was uncovered between RSA and RRBs $F(1, 113) = 3.96$, $p < 0.049$, $r^2 = 0.03$, indicating that more RRBs were associated with greater physiological dysregulation. Analyses also revealed that both RRBs ($b = 0.78$, $p < .001$) and RSA ($b = 2.24$, $p = .02$) were significant predictors of anxiety $F(2, 112) = 18.08$, $p < .001$, $r^2 = 0.24$. The indirect effect of RSA on anxiety through RRBs, however, was nonsignificant ($b = -1.06$ [CI: -2.54-0.10]).

Conclusions: The hypotheses were partially supported. Results provide further evidence for the notion that greater physiological dysregulation is associated with more RRBs. In constrast to hypotheses, however, results suggest that more anxiety is associated with better physiological regulation, controlling for RRBs. Although there were links between RSA and both RRBs and anxiety, RRBs did not explain the association between RSA and anxiety. Rather, RRBs explained additional variance in anxiety over and above RSA alone. Therefore, physiological dysregulation seems to affect anxiety, but does not do so via increased RRBs.

76 **183.076** Experiences of Seeking for Assessment and Diagnosis of Autism Spectrum Disorder in Vietnam

H. S. Vu[1]*, H. Hoang*[1]*, G. Le*[1] *and N. N. Tran*[2]*, (1)Center for Creative Initiatives in Health and Population, Hanoi, Viet Nam, (2)Administration for Medical Service, Ministry of Health, Hanoi, Viet Nam*

Background:
Early identification and accurate diagnosis enables early intervention, which leads to improved quality of life of individuals with autism spectrum disorder (ASD). In Vietnam, especially in provinces, there is little understanding about when care-givers of young children have first concern about their children, where and when they seek for assessment services for their children, and how their children are assessed, what parents think about the quality of services. This online survey has been carrying out in order to provide data for programmers and policy makers in efforts to enhance services for the children with ASD.

Objectives:

- To describe the experiences of parents of children with ASD in seeking for assessment and diagnosis services for their children.
- To explore some factors that might influence to the early identification and seeking for assessment services of parents of children with ASD.
- To provide suggestions to improve early identification and assessment services

Methods:

An online survey has been carrying out nation-wide with parents of children who received diagnosis of ASD since early October, 2017 to end October, 2017 using surveymonkey platform (https://www.surveymonkey.com). This survey has been promoting mainly through social media: facebook, and through sending email to parents.

Results: Two weeks after launching the survey, 380 parents completed fully the questionnaires. Preliminary analysis indicated that parents began to be concerned about their children from 3 months of age at the earliest to latest time of 60 months. On average, parents in this study began to be concerned about their children at the age of 22.4 months. On average, parents waited 3.4 months from when they started to have concerns to when they sought out assessment and diagnosis. More than half of parents (51%), sought assessment at specialist department directly at tertiary hospital of pediatrics. One average, parents travelled 86 km to access assessment clinics for their children. Less than 10% of parents were introduced and referred for assessment services from health professionals. Nearly half (46%) children were assessed less than 30 minutes and nearly 90% respondent received conclusion of assessment and diagnosis during the day their children were assessed. Only 35% of respondents agreed that professionals spent enough time to assess their children. About one third agreed that professionals provided enough time to explain assessment results and information to them. 56% parents thought that assessor had good knowledge on autism. About 15% did not believed in the conclusion of diagnosis. We will continue to run the survey for two more week and carry out further analysis to compare between rural and urban respondents, as well as socio-economic groups.

Conclusions: There are some concerns about the quality of assessment and diagnosis services and lack of referrals within health system. Greater effort, including develop national guideline, is needed to improve the accessibility and quality of assessment and diagnosis for ASD.

77 **183.077** Gender Differences in Autism Spectrum Disorder Characterization within a State-Wide Community-Based Sample

E. Clarke[1]*, C. E. McCormick*[2] *and S. J. Sheinkopf*[3]*, (1)Rhode Island Consortium for Autism Research and Treatment, Providence, RI, (2)Human Development and Family Studies, Purdue University, West Lafayette, IN, (3)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI*

Background: Since first described by Kanner, autism spectrum disorder (ASD) has been conceptualized as a predominately male condition. However, the relationship between ASD and gender is more nuanced than previously assumed. Males are more likely to receive an ASD diagnosis than females with equal symptomatology, and females are diagnosed later in life than males (Mandy et al., 2011). This female under-identification may result from gender-specific behavioral profiles in ASD, and a lack of understanding of the female behavioral profile (Dworzynski et al., 2012).
Objectives: To evaluate potential differences in behavioral characteristics and diagnostic outcomes across gender in a community-based sample.

Methods: This study analyzed data from males (n = 1128) and females (n = 335) ages 2-69 years enrolled in the Rhode Island Consortium of Autism Research and Treatment (RI-CART), a state-wide community-based sample. Enrollees had or suspected an ASD diagnosis, came from varied racial and socioeconomic backgrounds, and lived in southern New England. To join RI-CART, enrollees completed behavioral and cognitive measures including the ADOS-2, VABS-II, and KBIT-2.

Results: Female RI-CART enrollees had significantly higher KBIT-2 scores $F(1, 274) = 4.552$ $p = .034$, $\eta^2 = .016$, VABS-II overall scores $F(1, 1020) = 6.297$, $p = .012$, $\eta^2 = .006$ and social skills subdomain scores $F(1, 1028) = 8.003$, $p = .005$, $\eta^2 = .008$. VABS-II daily living skills domain scores and SRS-2 overall scores did not significantly differ by gender. Amongst participants with a community diagnosis, females had a significantly higher age of diagnosis $F(1, 560) = 7.47$, $p = .006$, $\eta^2 = .013$. RI-CART enrollees of both genders with a community diagnosis of ASD had higher ADOS comparison scores than enrollees without a community diagnosis $F(1, 1024) = 196.97$ $p < .001$, $\eta^2 = .005$. The interaction between community diagnosis and gender was significant. Male enrollees without a community diagnosis had significantly higher ADOS comparison scores than their female counterparts—in contrast, the ADOS comparison scores of enrollees with a community diagnosis did not significantly differ across gender $F(1, 1204) = 5.479$ $p = .019$, $\eta^2 = .019$.

Conclusions: Female RI-CART enrollees had significantly higher age of diagnosis than male enrollees, as well as higher KBIT-2, VABS-II social skills subdomain, and overall scores. These findings support the idea of a female-specific ASD behavioral profile. This profile may also contribute to the significantly lower ADOS-2 comparison scores in females questioning an ASD diagnosis. Better verbal, social, and adaptive skills could cause parents and clinicians to under-identify females with ASD. The female profile seen in this study does not mirror the profile identified by some prior studies; this may be due to heterogeneity of the RI-CART sample (Fraizer et al., 2014). Future research should clarify the characteristics of the female behavioral profile, as well as the breadth and magnitude of the gender discrepancy in ASD diagnoses.

78 **183.078** Identifying ASD and Comorbid Conditions: Joint Use of the SDQ and CSBQ

B. Barger[1]*, D. Roberts*[2] *and A. Roach*[1]*, (1)Georgia State University, Atlanta, GA, (2)GA State University, Atlanta, GA*

Background:

There are many screeners designed to identify developmental disabilities, externalizing, and internalizing conditions. However, many existing studies are limited by small sample sizes, focus on single instruments, are limited in the numbers of conditions considered, and often use of cut-off scores of other screeners or assessments, rather than actual diagnostic groups, as predicted outcomes.

Objectives:

This study investigates the predictive validity of a measure of externalizing and internalizing conditions, the Strengths and Difficulties Questionnaire (SDQ), and a measure of problems commonly seen in children with developmental disabilities, the Children's Social Behavior Questionnaire (CSBQ). Specifically, in a group of children with ASD, developmental delays (DD), and intellectual disabilities (ID), we hypothesize that the SDQ externalizing subscales would most strongly predict conduct problems and co-morbid attention deficit disorder (ADD), the SDQ internalizing subscales would most strongly predict co-morbid anxiety problems and depression, and CSBQ scales would most strongly predict

ASD diagnosis.

Methods:

We used national data from the Survey of Pathways to Diagnosis and Services to examine the predictive validity of the SDQ externalizing (conduct and attention problems) and internalizing (emotion and peer problems) sub-scales, and the CSBQ subscales (behavior/emotions not in tune to social environment, social contact/interest, orientation problems, social information processing, stereotypy, fear/change-resistance) in children with ASD, DD, and ID (n=2370). Analyses were weighted and stratified binary logistic regression models predicting the following separate outcome variables: parent reported ASD diagnosis, conduct problems, ADHD, anxiety problems and depression. All models statistically controlled for the following variables: gender; federal poverty level; age; race/ethnicity (White, Black, Hispanic, Other); maternal education; insurance status (private, public, and none); and English Language status (English speaking, non-English speaking).

Results:

Results of logistic regression generally supported the validity of the SDQ externalizing and internalizing subscales in groups of children with ASD, DD, and ID: Specifically, the SDQ conduct problems subscale was the only SDQ scale predictive of conduct problems (aOR = 1.43 95%CI[1.14-1.80]); the SDQ attention problems scale was the only SDQ scale predictive of ADHD (aOR = 1.43 95%CI[1.27-1.60]); the SDQ emotion problems scale was the only SDQ scale predictive of depression (aOR = 1.41 95%CI[1.25-1.60]) and anxiety (aOR = 1.41 95%CI[1.22-1.63]). The SDQ peer problems (aOR = 1.17 95%CI[1.01-1.37]), conduct problems (aOR = 0.74 95%CI[0.61-0.89]), and prosocial (aOR = 0.70 95%CI[0.60-1.80]) scales also predicted ASD diagnosis.

The CSBQ scales orientation problems positively (aOR = 1.08 95%CI[1.00-1.17]) and fear/change-resistance negatively (aOR = 0.84 95%CI[0.72-0.98]) predicted co-morbid ADD; social contact/interest (aOR = 0.90 95%CI[0.82-0.98]) negatively predicted comorbid depression; fear/change-resistance (aOR = 1.23 95%CI[1.01-1.49]) positively predicted ASD diagnosis.

Conclusions:

Data from this study indicates that some SDQ subscales may be useful for identifying externalizing and internalizing conditions in children with ASD, DD, and ID. Future research should determine whether the specific subscales versus the broader externalizing and internalizing subscales are preferred in this population. Furthermore, more research on the clinical utility of the CSBQ subscales is needed.

79 **183.079** Is the ADOS a Useful Instrument to Help in the Diagnosis of ASD Women?

L. Boada[1], *M. L. Dorado*[1], *P. Hernández*[1], *L. López*[1], *A. Alcón*[1], *M. Burdeus*[1] *and M. Parellada*[2], *(1)Hospital Universitario Gregorio Marañón. Child and Adolescent Psychiatry. IISGM. CIBERSAM, Madrid, Spain, (2)Fundación Investigación Biomedica Gregorio Marañon, Madrid, Spain*

Background:

In the last recent years there is a growing amount of scientific literature that shows the different clinical manifestation of ASD symptoms in women compared to men. It is well known that female-specific manifestation of autistic features fits imperfectly with current, male-based conceptualizations of ASD (Hiller et al. 2014;Lai et al. 2015).

Compared to males, females with ASD are: 1) less likely to have externalizing behaviours, and are more vulnerable to internalizing problems, such as anxiety, depression and eating disorders (Mandy, 2012; Huke, 2013); 2) have a greater social motivation (Sedgewick et al. 2015) 3) better non-verbal communication (Rynkiewicz et al. 2016) and 4) score lower on measures of repetitive and stereotyped behaviour (Van Wjingaarden-Cremers et al. 2014).

For these reasons, females are at substantially elevated risk of going undiagnosed: frequently mislabelled or missed entirely (Lai and Baron-Cohen 2015). Thus, many females who, if skillfully assessed, would meet full diagnostic criteria for ASD, never receive a ASD diagnosis.

Objectives:

1) To compare scores in selected ADOS items between men and women (based on previous literature): gestures, eye-contact, facial expression, prosody, stereotyped language, imagination, stereotypes and mannerisms, sensory abnormalities, restrictive interest, hyperactivity and anxiety. This analysis will be performed in a sample of 100 women and 100 men in whom ADOS has been administered in the last 8 years.

2) To study the agreement between ADOS cut-off label and the final clinical judgement.

Methods:

200 participants (100 girls and 100 boys matched by chronological age and secondary, when possible, by mental age) evaluated, from April 2009 to September 2017, in a Child and Adolescent Psychiatry Department of a General University Hospital in the context of one of the following: 1) diagnostic evaluation 2) to treat comorbidity or 3) participating in different research projects.

Procedure:

The ADOS was administered individually by a clinician with the appropriate reliability for the administration of the instrument. The evaluation was video-recorded. All the ADOS were immediately scored at the end of the evaluation. Final diagnosis was determined by clinical psychologists and psychiatrists with extensive experience in ASD based on all available information, including (always) full psychiatric and developmental interviews with parents or guardians (ADI-R when necessary), unstructured observation of the child, review of previous medical and educational records and ADOS scores. The diagnosis was therefore established following standard recommendations (Volkmar et al 2014) based on DSM-IV-TR ASD criteria (before 2013) criteria and/or DSM 5 criteria (after 2013).

Results: At the present moment all the evaluations have already been conducted and data are being incorporated in a database. We will conduct the statistic analyses during the next month.

Conclusions:

ASD girls are at risk of receiving non-spectrum classification in ADOS or ADOS-2 while their developmental history and clinical manifestations confirm ASD.

It could be the case that future editions of evaluating tools as ADOS need to contemplate differed cut-off scores for girls and boys. We intend to provide data to help with the discrimination of symptoms or behaviors that are differentially expressed by girls and boys.

80 **183.080** Laboratory and Home-Based Assessment of Electrodermal Activity in Individuals with ASD

M. S. Goodwin[1], *I. R. Kleckner*[2], *R. M. Jones*[3] *and C. Lord*[4], *(1)Northeastern University, Boston, MA, (2)University of Rochester Medical Center, Rochester, NY, (3)Weill Cornell Medicine, New York, NY, (4)University of California Los Angeles, Los Angeles, CA*

Background:

Sweat secretion from the skin is modulated by postganglionic sympathetic fibers surrounding eccrine sweat glands. Because eccrine sweat glands receive only excitatory sympathetic nerve impulses, electrodermal activity (EDA) constitutes a purely sympathetic response. The most widely studied property of EDA is skin conductance, which can be quantified by applying electrical potential between two points of skin contact and measuring resulting current flow between them. Changes in EDA has been widely used as an objective peripheral index of cognition, arousal, emotion, and attention in the general population since it results from neuronal activity in the amygdala, premotor cortex, pre-frontal cortex, hypothalamus, reticular activating system, and hippocampus. However, because EDA recordings are also influenced by non-autonomic factors such as thermoregulation, metabolic demand, participant movement, electrical noise, and other artifacts, it is critical to implement rigorous, well-defined, and replicable quality control procedures for selecting data prior to conducting inferential statistical testing.

Objectives:

Our objectives were threefold. First, we sought to develop and evaluate a quality control procedure for automatically selecting EDA data for subsequent comparative testing. Second, after applying our procedure to identify valid segments of EDA data, we evaluated EDA responses across laboratory and in-home settings. Third, we conducted preliminary analyses on EDA reactivity and its association with a variety of experimental tasks in laboratory settings, over repeated measures in the home, and in relation to day-to-day fluctuations in child irritability as rated by parents using a smartphone.

Methods:

Twenty children and adolescents (5 females, range 5-13 yrs, M=8 yrs) with a confirmed diagnosis of ASD (ADOS calibrated severity score, M=7.9, SD=1.8) were observed repeatedly over an 8-week period in both laboratory and home settings while their EDA was wirelessly recorded with the Affectiva Q sensor and their day-to-day fluctuations in irritability was rated by parents using a smartphone.

Results:

First, starting with 181 hours of raw EDA data collected in the study, our automated quality control procedure identified 120 hours of valid data across the 20 participants, yielding, on average, 6 hours of quality data per participant across an average of 4.6 recording days. Second, EDA responses discriminated between a variety of negative vs neutral affect-inducing tasks in the laboratory (Brief Observation of Social Communication Change, Purdue Pegboard, passive movie watching, and an iPad puzzle). Third, patterns of EDA data identified individual differences within and between children with ASD assessed over 7-10 days in home settings based on tonic level, variability, and the ratio between sympathetic reactivity (increasing slope) and recovery (decreasing slope). Fourth, using Hierarchical Linear Modeling, mean and standard deviation EDA was found to predict daily ratings of irritability at *p*=0.002 and *p*=0.043, respectively.

Conclusions:

Being able to reliably and validly obtain peripheral measures of autonomic arousal from individuals with ASD in an untethered way in both laboratory and natural environments over time enables an efficient and scalable way to gather biomarker data that could be used in diagnostic, phenotypic, and clinical/intervention explorations in autism and related neurodevelopmental disorders.

81 **183.081** Males and Females with ASD: A Gender Comparison between Cognitive and Behavioral Profiles

A. Bentenuto[1], *A. Peripoli*[2], *I. Landi*[3], *N. Mazzoni*[1], *T. Del Bianco*[1], *I. Basadonne*[1], *L. Carrieri*[2], *S. Cainelli*[2] *and P. Venuti*[1], *(1)Psychology and Cognitive Science, University of Trento, Rovereto, Italy, (2)University of Trento, Rovereto, Italy, (3)Bruno Kessler Foundation, Trento, Italy*

Background:

Recent research suggest that some of the characteristic traits of the Autism Spectrum Disorder have different expression in males and females (Dworzynski et al., 2012). Accordingly, it has been proposed that the gender prevalence might not be so unbalanced and that girls with ASD are actually under-diagnosed or mis-diagnosed (Gould & Ashton-Smith, 2011). Few studies have investigated the gender differences in people with ASD, but conflicting results have often been reported (Bőlte et al., 2011; and Kumazaki et al., 2015; Koyama et al., 2009). In general, females with high-functioning ASD can camouflage their autistic characteristics more successfully than males. Furthermore, females perform better in working memory tasks and exhibit lower level of repetitive and respective behavior than males. (Bőlte et al.,2011; e Kumazaki et al., 2015; Koyama et al., 2009). Besides, males have higher spatial- visual skills than females.

Objectives:

In the present study, we compare the cognitive and behavioral profiles of a group of 29 males and 29 females with ASD for a total of 58 participants. (Chronological age M = 9y, SD = 7y, 5m)

Methods:

Participants were administered with a complete assessment in a clinical center located in the Nord of Italy. The cognitive profile have been assessed with the Griffiths Mental Development Scales (GMDS) or Wechsler Scales, according to participants' age. The behavioral profiles included the subscales of the Autism Diagnostic Observation Schedule-Second Edition (ADOS-2).

Results:

Preliminary analysis on a total of 30 participants (15 males and 15 females) show that females obtained higher score in “Locomotion subscale” of GMDS (t = 1.8581, df = 9.9307, p-value = 0.04651) and in Performance Intelligence Quotients (PIQ) of the Wechsler Scale (t = 3.313, df = 7.5923, p-value = 0.01147).We did not find any significant sex-related difference ADOS total score (i.e. males and females display the same level of social communication impairment). However, results of the Principal Component Analysis applied on some index of ADOS (total score, Social Affect Area and Restricted and Repetitive Behavior) showed lower levels of restricted interests in females. .

Conclusions:

These preliminary results suggest the existence of cognitive and behavioral differences between females and males with ASD. These findings have important implication at a clinical level, as a more advanced understanding of the developmental trajectory in females with ASD would increases the possibility of adopting personalized management and defining treatment approaches specific for females with this disorder.

82 **183.082** Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R) Validation in Portugal: Preliminary Results

C. Almeida[1] *and D. L. Robins*[2]*, (1)PIN, Carcavelos, Portugal, (2)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Autism Spectrum Disorders (ASD) are lifelong developmental disorders, and early intervention is crucial for positive outcomes. ASD early screening in low-risk samples has been recommended as a strategy to promote early diagnosis, which facilitates early intervention. Screening procedures in Portugal are not yet common, which delays detection for many children. In order to increase ASD screening, a study using the Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R) has been implemented in pediatric and childcare settings.
Objectives: The main goal of this study is to establish preliminary validity for the M-CHAT-R in Portugal as a screening tool for low-risk toddlers.

Methods: Toddlers are recruited from two sources: childcare centers and pediatric check-ups. To date, 563 toddlers between 15 and 31 months (*m*=22.84, *SD*=4.23) were screened with M-CHAT-R. Parents of toddlers at risk on M-CHAT-R completed the M-CHAT-R Follow-up as an interview, and those who continued to show risk completed an evaluation using Autism Diagnostic Observation Schedule (ADOS), Autism Diagnostic Interview Revised (ADI-R), and Griffiths Mental Development Scale.

Results: Pediatric providers were reluctant to join the study. The majority of participants (80%) were screened in the daycare setting. From the 451 screened in daycare, 41 were positive (9.1%). After the Follow-up, eight continued to screen positive and four were diagnosed with an ASD, two had other developmental delays, and two were typically developing. From the 112 toddlers screened in pediatricians' settings, ten were positive (8.9%), after the Follow-up three continued to screen positive; one was diagnosed with ASD, one had a developmental delay, and one was typically developing. In both groups, the prevalence of ASD detected was 1 in 112.

Conclusions: Professionals from daycares were more receptive to screen for ASD than pediatricians during check-ups. Across the two groups, the M-CHAT-R performed similarly (9.1 vs 8.9% screened positive initially, similar ASD rate detected), suggesting that the setting does not impact the performance of the screening tool. ASD rates were consistent with other screening studies (Robins et al., 2014). Given the reluctance of many pediatric providers to incorporate routine ASD screening into well-child check-ups, daycare is a viable alternate setting. Portugal continues to require more information and awareness about ASD screening as an essential way to detect ASD and start early intervention as young as possible in order to improve children's outcomes. Additional education for pediatric providers may help doctors understand the value of ASD screening in low-risk samples.

83 **183.083** On the Potential of Automated Emotional Facial Expression Recognition for Screening/Diagnosis of ASD: Evidence from Comparing Human Vs. Machine Detection of Emotional Expressions of High Functioning Young Children with ASD

M. Gyori[1]*, Z. Borsos*[2]*, K. Stefanik*[1]*, J. Csákvári*[1] *and F. Varga*[1]*, (1)ELTE University, Budapest, Hungary, (2)Eotvos Lorand University Barczi Gusztav Faculty of Special Needs, Budapest, HUNGARY*

Background: Improving early recognition of ASD has been a key focus of research and development in the last decades. Recently, technological developments seem to have given new impetus to it. Both clinical and experimental studies indicate differences between emotional facial expressions of neurotypical (NT) children and children with ASD. Although differences are often subtle and varying, screening/diagnostic technologies may potentially be able to exploit them.
Objectives: The present work was aimed at exploring whether commercially available emotional facial expression recognition technology has a potential for being a part of technologically-aided early screening/recognition of ASD, vis-á-vis recognizing emotional facial expressions by human coders. This work is a part of a larger research-and-development project with the objective of developing and validating a multi-modal, social serious game-based digital system for screening for ASD in 3-6 year old high functioning (HF) children.

Methods: Video recordings of 13 HF ASD children (mean age 58.4 months, range 43-70) and 13 NT children (mean age 57.15 months, range 43-68) were analyzed; all ASD children had a clinical diagnosis confirmed by ADOS and ADI-R; all NT children had negative ADOS and ADI-R results. There were no significant differences between the two groups along age and IQ. Each video-recording showed the face of a child while playing with the fully playable prototype of the screening serious game under development, but did not show any content of the game. Three sessions were selected from the recording for analysis: from the beginning the play session (140 secs), from the middle (195 secs), and from the closure of the game (15 secs). Each video-recording was analyzed by a machine system (Noldus FaceReader v5.1, Noldus Information Technology) and by two independent human raters. For human coding, we adapted the judgment-based emotion coding system of Kring és Sloan (2007; Facial Expression Coding System, FACES). Although sign-vehicle-based human emotion coding systems (such as the Facial Action Coding System by Ekman & Friesen, 1978) seem more accurate, their time and resource consumptiveness makes them imperfect tools in screening contexts. First, inter-rater reliability was calculated for human, test-retest reliability was calculated for machine codings. Secondly, we intended to compare the two groups along the intensities of the displayed emotions, based on human and machine codings, separately.

Results: Human coding of emotional facial expressions showed very poor inter-rater reliability, on both ASD and NT data, rendering any further analysis of this dataset methodologically unsupported. Machine coding, as expected, showed practically total test-retest reliability, and group comparisons showed significant differences in mean intensities of two emotions (scared, surprised), ASD group showing these more intensively.

Conclusions: While human emotional facial expressions coding has proven to be unreliable in this study, machine coding was practically totally reliable and was able to reveal ASD/NT differences. These are consistent with findings from earlier studies on emotion expressions in children with ASD. Although further confirmation and resolving methodological issues are needed for firm conclusions, our results suggest that automated facial expression recognition may potentially play a role in technologically-aided early screening/diagnosis of ASD.

84 **183.084** Peripheral Sympathetic and Parasympathetic Activity in ASD with and without Comorbid Anxiety

V. Parma[1] *and J. D. Herrington*[2]*, (1)William James Center for Research, ISPA - Instituto Universitário, Lisbon, Portugal, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Anxiety disorders are one of the most common comorbidities among individuals with autism spectrum disorder (ASD). While anxiety disorders have been thoroughly characterized from a psychophysiological perspective, this is not yet true for the psychophysiological manifestations of anxiety in ASD. Both pathologies are underlined by abnormal physiological activity.
Objectives: To assess similarities and differences in the peripheral sympathetic (i.e., electrodermal) and parasympathetic (i.e., heart rate

variability) activity of children with ASD with and without comorbid anxiety and matched controls.

Methods: Seventy-five children and adolescents between 7 and 17 years of age were recruited. Thirty-seven were diagnosed with ASD, of which 22 with comorbid anxiety. Thirty-eight were typically developing controls (TDC), of which 16 were diagnosed with one or more anxiety disorders. All watched natural-scene movies while the physiological activity was recorded.

Results: Peripheral sympathetic activity within individuals with anxiety was found to be higher in TDC as compared to the ASD group. Higher vagal activity was reported in the TDC non-anxiety group as compared to both ASD groups. A multinomial regression model including such physiological measures and parent reports on anxiety (SCARED) and ASD symptoms (SCQ) allowed to classify 73% of cases across the 4 groups.

Conclusions: Besides supporting the inclusion of psychophysiological indicators when examining the relationship between anxiety and ASD, this study highlights the need for more research on how to best conceptualize, evaluate, and treat children with ASD with and without comorbid anxiety.

85 **183.085** Priorities Established By the Combating Autism Act for Improving ASD Identification: Looking Beyond Ideas and Instruments Towards Implementation

***P. Doehring**, ASD Roadmap, Chadds Ford, PA*

Background: The 2006 Combating Autism Act or CAA is the most ambitious ASD national research strategy to date. In response to growing concerns about ASD's prevalence and impact, CAA created the InterAgency Autism Coordinating Committee or IACC to establish priorities for federal research funding. Between 2008 and 2013, IACC helped to direct $1.8 billion towards these priorities. The lack of significant improvement in timely and accurate identification, especially for traditionally underserved groups, has led researchers and advocates to question these priorities. Would a greater focus on implementation, disparities, and capacity building be more effective in closing gaps in ASD identification?

Objectives: To establish how much federally-funded research addressing identification between 2008 and 2013, and the publications which resulted, sought to either (1) explore theoretically relevant factors, (2) validate instruments, or (3) test immediately applicable strategies to close gaps, improve implementation, or build capacity.

Methods: Using the Autism Research Database, we identified all federally-funded research grants between 2008 and 2013 that potentially addressed ASD identification. In addition to projects explicitly focused on ASD screening and diagnosis, we included potentially overlapping projects addressing services, lifespan issues, and infrastructure. We have also begun to assemble all publications arising from these grants, using existing federal databases supplemented by Pubmed/Psychinfo searches. We have begun to conduct title, abstract, and full-text reviews of these research projects and publications to identify the subset that clearly focused on identification. Within this subset, we have begun to distinguish between those addressing theoretically relevant factors, those validating instruments, and those testing specific and immediately applicable strategies. Within this last group, we are categorizing articles according to population, focus, and setting.

Results: Almost $500 million of federal research funding addressed the IACC priorities related to Diagnosis, Services, Lifespan, and Infrastructure between 2008 and 2013. Preliminary analyses indicate substantial variability in the extent to which federal funding was directed towards specific and immediately applicable tools or approaches to improve identification. For example, at least 25% of federal research funds targeting Diagnosis addressed questions only of theoretical importance (for example, examining potential biomarkers of ASD). IACC also fell far short of certain key targets related to diagnosis (for example, successfully allocating less than 5% of the desired funding towards improved identification of ASD in adults). Projects clearly intended to immediately improve identification are much more likely to focus on validating tools than addressing disparities or barriers to implementation. Additional analyses are underway to establish whether similar patterns are evident among the research publications generated by these projects.

Conclusions: Available analyses indicate that a relatively small proportion of the research funded by the NIH between 2008 and 2013 tested a specific and immediately applicable tool or approach to improving ASD identification. The paucity of research addressing disparities and implementation barriers limits the immediate impact of the knowledge gained thus far. Implications for future research and policy are discussed.

86 **183.086** Prospective Validation of Molecular Subtype Diagnostics for Autism Spectrum Disorders and Neurodevelopmental Disorders

***R. Burrier**[1], D. G. Amaral[2], E. Donley[1], J. King[3], A. Smith[3], P. West[3], L. Feuling[3], M. Ludwig[3], D. B. Sugden[3] and B. Smart[3], (1)Stemina Biomarker Discovery, Madison, WI, (2)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (3)Stemina Biomarker Discovery, Inc., Madison, WI*

Background:

Autism is a complex neurodevelopment disorder with underlying genetic, metabolic, and environmental factors leading to individual differences in clinical presentation and response to therapies. Earlier diagnosis of children with autism spectrum disorder (ASD) improves outcomes through the early initiation of therapeutic interventions. Based on previous metabolic profiling of ASD in three clinical studies involving more than 500 subjects, we postulated that metabolites can define subpopulations or metabolic subtypes of ASD. These subtypes could then be used to stratify the ASD population based on metabolic differences. Initial analysis of metabolomic data were used to design the Children's Autism Metabolome Project (CAMP, ClinicalTrials.gov Identifier NCT02548442); the largest metabolomics study of autism conducted to date. CAMP has enrolled over 1,000 pediatric subjects, carried out metabolomic analyses of donated, fasting blood samples and is validating subtypes prospectively providing potentially actionable results. Metabolic subtypes have the potential to identify subjects that may benefit from specific dietary and pharmacological interventions.

Objectives:

The objective of this study is to prospectively validate metabolite-based diagnostics for neurodevelopmental disorders (ND), ASD and developmental delay (DD) where each subtype diagnostic identifies a subpopulation with high specificity. Evaluate the clinical performance of each diagnostic by testing plasma samples from subjects in the CAMP study consisting of ASD, DD and typically developing (TD) subjects.

Methods:

The CAMP study is being conducted at 8 locations. Diagnosis is based on Diagnostic and Statistical Manual of Mental Disorders (DSM-5) confirmed by research reliable Autism Diagnostic Observation Schedule (ADOS) for ASD and the Mullen scales of early learning for DD. Samples from 368 subjects (242 ASD, 40 DD, 87 TD) aged from 18 to 48 months were selected to set thresholds for each subtype diagnostic. Plasma from these subjects was analyzed using a quantitative assay for a panel of amine containing metabolites and these measurements were used to set thresholds for each subtype diagnostic. A second set of approximately 350 subjects that had not been previously measured were analyzed using the same quantitative method to determine the clinical performance of each subtype diagnostic.

Results:

Thresholds were set for five molecular subtype diagnostics for ASD or DD. Thresholds were also set for a subtype diagnostic for the diagnosis of ASD. A prospective analysis of 368 children aged from 18 to 48 months is underway and will be completed at the time of this presentation. We expect to validate several molecular subtypes of ND with a combined sensitivity exceeding 20% and a specificity of greater than 90%.

Conclusions:

The CAMP study provides the largest set of samples collected under procedures designed for the investigation of metabolic differences associated with NDs such as ASD and developmental delay (DD). This report focuses on the validation of a collection of molecular subtype diagnostics which reliably identify ASD and DD children in a prospective analysis. Each molecular subtype suggests altered levels of metabolites or an imbalance of metabolites which suggests possible interventions to improve outcomes.

87 **183.087** Psychometric Analysis of the Autism Spectrum Quotient Using Diagnostic Classification Modeling

E. G. Keenan[1]*, M. J. Madison*[2]*, J. J. Wood*[1] *and M. D. Lerner*[3]*, (1)Human Development & Psychology, University of California, Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background:

The Autism Spectrum Quotient (AQ), a widely-used self-report questionnaire measuring autism traits in adults, has reported good predictive validity and moderate to high internal consistency for its five subscales (Baron-Cohen et al., 2001). Factor analyses have not shown the AQ to be unidimensional; its use as a raw score measuring a single latent variable has been criticized (Lundqvist & Lindner, 2017). Items demonstrated a need for revision due to redundancies and negative point-measure correlations. To facilitate greater understanding of the AQ, examination of how each item contributes to its estimation of the latent variables it measures is needed.

To evaluate the psychometric properties of the AQ items and subscales, we used a diagnostic classification model (DCM), psychometric models designed to classify respondents according to specified categorical latent traits (Ravand & Robitzch, 2015). The categorical classifications of each latent trait provide maximum separation between groups based on item responses. While classical test theory models weight each item equally in raw scores, DCMs account for variable test item quality.

Objectives:

We aim to characterize psychometric properties of the AQ items and subscales using a DCM. We also aim to evaluate predictive validity of subscale classifications in comparison to raw subscale scores.

Methods:

200 undergraduates completed questionnaires, including the AQ, Perseverative Thinking Questionnaire (PTQ), and Patient Health Questionnaire (PHQ; a depression measure).

First, a unidimensional DCM was estimated with AQ as the single latent trait. A second DCM was estimated using the five subscales as latent variables. The relation between AQ classifications and other variables were assessed using independent-samples t-tests. A moderated regression was constructed to determine the impact of classifications on the relation between PTQ and PHQ.

Results:

The unidimensional model characterized 31.5% of participants as high traits (HT). HT participants had significantly higher PTQ and PHQ compared to those with lower traits (LT; both $p = .03$). The mean difference in probability for HT and LT participants endorsing an item was .16 (see Table 1 for details of the first 20 items).

In the five-attribute model, correlations between attributes varied, from negative correlations with Attention to Detail and all others, to positive correlations with Social Skills and Communication/Imagination (both $r > .9$), suggesting the AQ is not a unidimensional measure. Comparing the relative fits of unidimensional and five-attribute models using a chi-squared test, the five-attribute model had better fit ($p < .0001$).

While neither overall raw score (p=.17) nor HT grouping (p=.55) was significant in the moderated regression, classifications (but not raw scores) of Attention Switching and Attention to Detail subscales were significant (p=.004 and .02, respectively). Figure 1 illustrates Attention Switching as a moderator.

Conclusions:

Due to varied specificity in AQ items – “I tend to notice details that others do not” versus “I usually notice car number plates or similar strings of information” – the DCM model showed greater predictive validity in our moderated regression (illustrating attention as a moderator in the relation between perseveration to depression) than raw scores. Future research should examine the impact of item parameters on classical test theory.

88 **183.088** Quality of Life in Autism: A Systematic Literature Review

K. Evers[1,2,3]*, J. Maljaars*[1,2,3] *and I. Noens*[1,4]*, (1)Leuven Autism Research (LAuRes), KU Leuven, Leuven, Belgium, (2)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (3)Child Psychiatry, UPC-KU Leuven, Leuven, Belgium, (4)Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium*

Background: ASD is a life-long neurodevelopmental disorder with substantial impact on various aspects of daily-life functioning. However, the first articles evaluating quality of life in individuals with ASD were only published quite recently. Since then, the interest has grown tremendously, yielding highly diverse publications, both in terms of addressed research questions and ASD characteristics, but also in terms of quality of life measurements and results. Several researchers have reviewed quality of life publications in autistic individuals. The number of articles included

in each of those previous reviews varied between 11 and 16.
Objectives: We wanted to perform an extensive systematic review on quality of life in individuals with ASD, aiming to provide responses on the following questions: (1) Do autistic individuals have a lower quality of life?; (2) Which factors are associated with a lower (or higher) quality of life in individuals with ASD?; (3) How can we measure quality of life in those with ASD?.

Methods: This literature review consisted of multiple stages with a final set of 48 included publications: (1) the literature search, (2) screening all publications using a set of inclusion and exclusion criteria, and (3) extraction and coding of the relevant data.

Results: Quality of life appeared lower in individuals with ASD compared to normative samples, typically developing controls, but also in comparison to a broad range of clinical control populations. More problem behavior, higher ASD severity and lower adaptive functioning were clearly associated with poorer quality of life, but evidence on the effects of age and gender was highly mixed. Intelligence did not correlate with quality of life. A broad range of measurements was used, but mostly questionnaires were administered from autistic individuals themselves, or a proxy. Parents or other proxies reported lower quality of life compared to the individuals with ASD themselves, but moderate intra-class correlations were found between proxy- and self-reports.

Conclusions: Quality of life gained increasing importance, both as treatment goal and in the context of treatment evaluation. The concept has proven its value in other clinical populations, in shifting the attention from problems to individuals' strengths and in emphasizing their subjective perspectives. This extensive literature review has demonstrated the relevance in the context of individuals with ASD, but also pointed towards some pitfalls. An ASD-specific QoL instrument has not been developed yet, and the currently used measurements include a highly diverse set of quality of life domains.

89 **183.089** School Psychologists Use of Evidence-Based Assessment Practices for the Examination of Autism Spectrum Disorder

M. Fraser[1] *and L. J. Dilly*[2]*, (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Atlanta, GA*

Background: Within the United States, public school assessments first identify a significant portion of children with ASD (Pettygrove et al., 2013). While the use of Evidence-Based Assessment (EBA) practices for the examination of ASD are widely accepted and endorsed by leadership organizations such as the National Association of School Psychologists (NASP) (Falkmer, Anderson, Falkmer, Horlin, 2013; Esler, & Ruble, 2015), emerging research examining the practices of school psychologists in the assessment of ASD indicates disparate practices (Aiello, Ruble, & Eslerc, 2017).
Objectives: This study examined the number of school psychologists' who utilize comprehensive, evidence-based assessment (EBA) practices for ASD, which was defined as assessments including an interview, cognitive/developmental measure, adaptive measure, and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2). Additionally, the use of the ADOS-2 was of particular interest. Use of the ADOS-2 across geographical locations, school district population size, evaluator training level, and evaluator years of experience was considered.

Methods: The survey created for this research study was developed by a team of clinicians and researchers in order to collect demographic information and school psychologists' assessment procedures for students with ASD. The survey was emailed to 557 school psychologists in Georgia. The response rate was 61%. IDEA Section 618 data records indicate in 2013 there were 720 school psychologists, indicating the respondents represent approximately 47% of school psychologists in Georgia.

Results: Thirteen respondents (3.82%) reported adherence to EBA. Related to the ADOS-2, 71 respondents reported regular use. There was a significant effect of the geographical location on the use of the ADOS-2 [$F(2, 287) = 6.70$, $p = 0.001$, $d = 1.843$]. There was a significant difference for participants located in suburban ($M=2.55$, $SD=1.448$) and rural areas ($M=1.89$, $SD=1.298$).

There was a significant effect of the student population size on the use of the ADOS-2 at the $p<0.05$ level [$F(5, 284) = 4.61$, $p = 0.000$, $d = 0.972$]. There was a significant difference for a student population size of 75,001-100,000 ($M=3.35$, $SD=1.496$) from a population of less than 10,000 ($M=1.88$, $SD=1.333$), 25,001-50,000 ($M=2.11$, $SD=1.319$), and of over 100,000 ($M=2.19$, $SD=1.210$).

There was not a significant effect of evaluator level of training or evaluator years of experience on the use of the ADOS-2 ($p = 0.514$; $p = 0.618$).

Conclusions: Few respondents indicated adherence to EBA, suggesting further investigation into the barriers impacting use, need for professional development, and practicality of current EBA in the school setting. Specifically, use of the ADOS-2 appears to differ slightly in Georgia across geographical locations and population size, while evaluator level of training and years of experience did not influence the use of the ADOS-2. Evaluators in larger, suburban districts tended to use the ADOS-2 more frequently where there may be more financial resources. Results suggest barriers may be present at the systems-level that impact the likelihood of regular use. Professional development and consultation with leadership personnel regarding the use of the ADOS-2 as part of EBA may be warranted.

90 **183.090** Screening for Autism Spectrum Disorder in a Naturalistic Home Setting Using the Systematic Observation of Red Flags (SORF)

D. Dow[1]*, T. N. Day*[2]*, C. Nottke*[2] *and A. Wetherby*[2]*, (1)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (2)Florida State University Autism Institute, Tallahassee, FL*

Background: While early detection of autism spectrum disorder (ASD) is critical for timely initiation of intervention, development of more effective screening tools is necessary to warrant a recommendation for routine universal screening (Campos-Outcalt, 2011). Time and resource constraints also limit screening procedures (Daniels et al., 2014), leading to delays in diagnosis until 4 ½ years of age (Baio, 2014). This is further exacerbated for non-white children in low-resource areas (Daniels & Mandell, 2013) due to limitations in accessibility of clinical services. Improved screeners are needed that not only effectively identify children at risk, but also offer increased feasibility for widespread use across community settings.
The Systematic Observation of Red Flags (SORF) is an observational measure that can be used by non-experts (e.g., paraprofessionals, undergraduate students) to detect risk for ASD in young children (Dow et al., 2016). Studying this measure in the home context could improve community-viable screening options accessible to more families, especially those with more limited resources.

Objectives: To examine psychometric properties of the SORF home measure for 18-24 month olds, including item-level performance and overall sensitivity, specificity, and recommended cutoff scores.

Methods: Preliminary analyses were conducted on a sample of 61 participants (31 with ASD, 14 developmental delayed, 16 typically developing) recruited by the FIRST WORDS® Project at Florida State University. A sample size of 217 will be completed at the time of presentation. The sample was randomly selected, stratified by race to optimally represent minority groups (i.e., 13% Black, 11% Hispanic, 9.5% Biracial). Receiver operating characteristic (ROC) curves and analysis of variance (ANOVA) were used to evaluate individual items and summary scores.

Results: Preliminary results based on the Composite summary score composed of best performing items suggest good discrimination between ASD and nonspectrum groups (AUC=.89), with high sensitivity and specificity (sensitivity=.90, specificity=.83). Group differences with large effect sizes were found between ASD and nonspectrum groups for all summary scores and social communication domain scores. Best performing items include *showing and pointing* (AUC=.83), *eye gaze* (AUC=.81), *nonverbal communication* (AUC=.81), and *more interest in objects than people* (AUC=.81).

Conclusions: Preliminary results support the utility of the SORF as an effective observational screening tool for ASD that can be used in a naturalistic home setting by non-experts. Data on individual item utility and required length of observation will be further analyzed in an effort to create a briefer measure to improve feasibility. Future studies will also examine the SORF's utility in a younger sample at 12-18 months, and in combination with parent report. Applying the SORF to the home context could provide a community-viable screening option accessible to more families, aiming to improve services for minority and low resource children and decrease delays in diagnosis of ASD.

91 **183.091** Sensitivity and Specificity of the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) in Acute Care Settings

N. Noonan[1,2]*, G. Righi*[3]*, R. McLean*[4]*, R. L. Gabriels*[5]*, M. Siegel*[6]*, K. Pedersen*[7] *and S. J. Sheinkopf*[8]*, (1)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, (2)E. P. Bradley Hospital, Providence, RI, (3)Brown Center for the Study of Children at Risk, Emma Pembelton, Providence, RI, (4)Brown University, Providence, RI, (5)Psychiartry & Pediatrics, University of Colorado School of Medicine, Aurora, CO, (6)Maine Medical Center - Tufts School of Medicine, Westbrook, ME, (7)Department of Psychiatry, Maine Medical Center, Portland, ME, (8)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI*

Background: ASD affects an estimated 1 in 68 children in the US (CDC, 2015) increasing substantially since the 1990s. Children with ASD often develop co-morbid psychiatric conditions (Simonoff et al., 2008), and often require acute psychiatric services (Mandell et al., 2008). Despite the need for specialized psychiatric services, this population is often hospitalized in general pediatric psychiatry units (Gabriels et al., 2012). These units may include assessment services, especially to guide disposition planning and service access (Mandell et al., 2005). Consequently, assessment measures designed for use in outpatient settings are used in acute care settings, at times with limited guidance from neurodevelopmental specialists. These tools may capture a unique snapshot of extreme behaviors related to a psychiatric crisis, calling into question the validity of the clinical findings, particularly for long term/developmental diagnoses.

Objectives: This study investigates the sensitivity and specificity of the ADOS-2 when administered in an acute psychiatric care setting.

Methods: Participants were selected from the Rhode Island Consortium for Autism Research and Treatment (RI-CART), a state-wide registry of individuals diagnosed with ASD or related neuro-developmental disorders. Selected RI-CART participants (n = 80; 70% male, Mean Age = 11.5, sd = 2.9) were enrolled in the registry while admitted to either a pediatric psychiatric inpatient unit (n = 11) or partial hospital program (n = 69); assessment was acquired during admission. Assessments included an ADOS-2 administered by a research-reliable examiner, and other cognitive (K-BIT 2), emotional/behavioral (SRS-2), and adaptive measures (VABS). Parents completed a demographics form. A confirmed diagnosis of ASD was indicated if participants medical charts contained an active diagnosis of ASD and ADOS-2 results were positive for ASD (n = 34). Additional data derived from the Autism and Developmental Disorders Inpatient Collaborative (ADDIRC; n = 736 with confirmed ASD diagnosis and positive ADOS-2; n = 178 with discordant clinical diagnosis and ADOS-2 scores) is being prepared and subsequent analysis will include: 1) more in-depth examination of demographics characteristics, 2) second sensitivity and specificity analysis with the full sample, 2) an examination of individual ADOS-2 items that reliably distinguish between ASD positive and ASD negative participants and, 3) a receiver operating characteristic (ROC) curve to examine how alternative algorithm cut-offs may increase the sensitivity and specificity of the ADOS-2 when used in acute care settings.

Results: Participants presented with numerous psychiatric comorbidities (mean = 2.7, range 1-5 psychiatric dx). Preliminary data include 51 Module 3 and 29 Module 4 ADOS-3 results. In this sample, the Module 3 algorithm produced a sensitivity of 36% and a specificity of 79%; Module 4 algorithm produced a sensitivity of 83% and a specificity of 71%. No differences in sensitivity and specificity were attributed to participants' gender (p = 0.17).

Conclusions: Results from these analyses suggest that sensitivity and specificity of the ADOS-2 may be lower in acute care compared to previous findings in outpatient samples. This, combined with upcoming analysis examining alternative algorithm cut-offs, aim to provide clinical diagnostic guidelines to improve the accuracy of the ADOS-2 when used in acute care.

92 **183.092** Sub-Dimensions of Impairments in ASD, Referring to Age, IQ and Gender – a Factor Analytical Analysis of the ASD-Net Database

N. Wolff[1]*, I. Kamp-Becker*[2]*, S. Köhne*[3]*, L. Poustka*[4]*, S. Roepke*[5]*, S. Stroth*[6]*, A. Langmann*[7] *and V. Roessner*[8]*, (1)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus Dresden, Dresden, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Schutzenstr 49, Germany, (3)Berlin School of Mind and Brain, Humboldt University Berlin, Berlin, Germany, (4)Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Goettingen, Goettingen, Germany, (5)Department of Psychiatry, Charite Berlin, Berlin, Germany, (6)Philipps University Marburg, Marburg, Germany, (7)Department of Child and Adolescent Psychiatry, , Psychosomatics and Psychotherapy, Medical Clinic, Philipps-University Marburg,, Marburg, IA, Germany, (8)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Dresden, Germany*

Background: Developmental Disorders, like Autism Spectrum Disorders (ASD) have their onset in early childhood and are characterized by a delay and a deviation in the development. It is further assumed that different autistic disorders (F84.0, F84.5, F84.1) cannot be categorially distinguished from one another, but should rather be arranged on one dimension. Therefore the question is raised how dimensions of different symptoms of ASD differ from each other depending on the applied Autism Diagnostic Observation Schedule (ADOS) module, age, gender, intelligence quotient (IQ) and the concrete ASD diagnose of the patient.

Objectives: Aim of the present talk is to specify separable dimensions of ASD by examining scores of the ADOS.

Methods: Using one of the largest internationally available samples, which is uniformly diagnosed according to gold standard (www.asd-net.de), data from N= 2613 patients (age 13.3± 10.4, IQ 97.4 ± 20.02) were analyzed. We applied factor-analytical analyses for each ADOS module and associate the observed factors with age, gender, IQ and diagnose of the patient. Further logistic regression analyses were applied to specify the forecasting power of the observed dimensions (factors).

Results: We observed that the numbers of factors vary depending on the applied module. In addition factors were very specifically associated with age, gender or IQ of the patients: while module 1 and 4 are for example multi-dimensionally dependent on different factors, we observed no association between age, gender or IQ for modules 2 and 3. In addition gender seems to influence factors of module 4 solely, while no influence was observed for module 1-3.

Conclusions: Based on the ASD-net database module-dependent sub-dimensions of the ASD symptomology could be identified which seem to have huge influence on the diagnostic process.

93 **183.093** Symptoms of ASD in Children and Adolescents with a Diagnosed Mood or Anxiety Disorder

A. Langmann[1]*, I. Kamp-Becker*[2]*, S. Köhne*[3]*, L. Poustka*[4]*, S. Roepke*[5]*, V. Roessner*[6]*, N. Wolff*[7] *and S. Stroth*[8]*, (1)Department of Child and Adolescent Psychiatry, , Psychosomatics and Psychotherapy, Medical Clinic, Philipps-University Marburg,, Marburg, IA, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Schutzenstr 49, Germany, (3)Berlin School of Mind and Brain, Humboldt University Berlin, Berlin, Germany, (4)Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Goettingen, Goettingen, Germany, (5)Department of Psychiatry, Charite Berlin, Berlin, Germany, (6)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Dresden, Germany, (7)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus Dresden, Dresden, Germany, (8)Philipps University Marburg, Marburg, Germany*

Background: Autism spectrum disorders (ASD) and mood/anxiety disorders are commonly diagnosed in children and adolescents. Differentiation between the two is a diagnostic challenge, as there are several clinical symptoms that occur in both groups of disorders. Current studies suggest that symptoms such as early onset of symptoms, fear of changes, abnormal social interaction and communication as well as stereotyped, repetitive behaviour do occur in both groups of disorders. Furthermore, ASD and internalizing disorders can occur as comorbid conditions. The diagnostic gold standard for ASD comprises standardized behavioural assessment with the Autism Diagnostic Observation Schedule (ADOS-2), a specific interview (Autism Diagnostic Interview, ADI-R) and thorough differential diagnostic assessments.

Objectives: The explorative study investigated the diagnostic accuracy of ADOS-2 and ADI-R as well as possible symptom constellations that might facilitate differentiation of the two groups on the basis of the diagnostic measures.

Methods: A subsample of the ASD-Net consortium (www.ASD-Net.de), comprising data from n=792 individuals (age mean 11.6±5.1, IQ mean 95.9±19.4, 74% male; n=792 ASD, n=146 internalizing disorders, i.e. ICD-10 diagnoses F 32; F 40.1; F 93.2 and others) was explored with respect to sensitivity, specificity, ROC-analyses of the ADOS-2 and ADI-R results considering age, IQ and gender differences. Discriminant analyses were conducted to explore similarities/differences in reported and observed symptoms on domain and item levels.

Results: First analyses show sensitivities of 72–89% and specificities of 72–93% for the ADOS-2, with 4.0 - 27.8 % false positive diagnoses with the ADOS and up to 55.4 % false positive diagnoses with the ADI-R.

Conclusions: Due to high symptom overlap between the investigated disorders a thorough diagnostic assessment conducted by experienced clinicians is crucial.

94 **183.094** The Autism Diagnostic Interview-Questionnaire (ADI-Q)

M. Huerta[1]*, S. Bishop*[2]*, L. A. Croen*[3] *and C. Lord*[4]*, (1)Felicity House, New York, NY, (2)University of California San Francisco, San Francisco, CA, (3)Division of Research, Kaiser Permanente, Oakland, CA, (4)University of California Los Angeles, Los Angeles, CA*

Background: The Social Communication Questionnaire (SCQ-L; Rutter, Bailey, & Lord, 2003) is a parent-rated autism screener that has been widely used in research. However, the SCQ-L is based on past behavior and like many ASD screeners, the utility of the instrument has been found to be affected by age and developmental level (Eaves et al., 2006; Chandler et al., 2007; Charman et al., 2007; Wiggins et al., 2007). Moreover, recent analyses of NDAR data has found the SCQ's sensitivity and specificity scores to be lower than originally reported; at the recommended cutoff score of 15, a sensitivity value of .64 (CI_{95} : 0.57; 0.69) and a specificity value of .72 (CI_{95} : 0.62; 0.81) were reported by Barnard-Brak and colleagues (2015). To address the limitations of the SCQ, a new caregiver-reported screening questionnaire was developed.

Objectives: The goals of this study are to develop and test an ASD research screening instrument that can be used to rapidly screen verbal children and adolescents, ages 5 to 18 years.

Methods: Previously collected ADI-R scores from two large samples of children and adolescents with ASD and non-ASD diagnoses, available through the University of Michigan Autism and Communication Disorders Center (UMACC) and Kaiser Permanente Northern California (KPNC), informed initial item development. To test the new instrument, named the Autism Diagnostic Interview-Questionnaire (ADI-Q), a new sample of 977 males and 287 females with ASD and non-ASD diagnoses was collected at UMACC, KPNC, and Cincinnati Children's Hospital Medical Center (CCHMC). Data were split into an initial test sample and a final validation sample. ADI-Q items were rank ordered by odds ratios and item distributions were examined to inform final item selection. Sensitivity and specificity values were analyzed using ROC analyses.

Results: The resulting instrument, the Autism Diagnostic Interview-Questionnaire (ADI-Q), consists of a 20-item measure. AUC values and sensitivity and specificity values were comparable to those of the SCQ-Lifetime. Results from the current analyses supported the use of unique algorithms and cutoffs for each sex.

Conclusions: The study presents a new ASD screening instrument, based on current behavior, that can have applicability to the participant recruitment efforts of a wide variety of research endeavors. Study results are discussed in light of the sex differences in the behavioral phenotype of ASD.

95 **183.095** The Female Phenotype of ASD – Same or Different to the Male Phenotype?

T. Schad-Hansjosten[1]*, I. Kamp-Becker*[2]*, S. Köhne*[3]*, L. Poustka*[4]*, S. Roepke*[5]*, V. Roessner*[6]*, N. Wolff*[7] *and S. Stroth*[8]*, (1)Department of Child and*

Adolescent Psychiatry and Psychotherapy, Central Institute of Mental Health, Medical Faculty Mannheim, Mannheim, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Philipps University Marburg, Schutzenstr 49, Germany, (3)Berlin School of Mind and Brain, Humboldt University Berlin, Berlin, Germany, (4)Child and Adolescent Psychiatry and Psychotherapy, University Medical Center Goettingen, Goettingen, Germany, (5)Department of Psychiatry, Charite Berlin, Berlin, Germany, (6)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Dresden, Germany, (7)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus Dresden, Dresden, Germany, (8)Philipps University Marburg, Marburg, Germany

---

Background: One of the most remarkable features of autism spectrum disorders (ASD) is the relation of male and female affected patients, which refers to 4-5:1 on average. In ASD *without* cognitive impairment the male:female relation is reported to be 10:1, while it is 1-2:1, in patients *with* cognitive impairment. With this in mind, a discussion arises scrutinizing whether the female ASD phenotype is identical with the male one and whether diagnostic instruments maybe underdiagnose female participants.

Objectives: The present talk aims to analyze this question by the help of a huge data base and with matched sample comparisons.

Methods: Using one of the largest internationally available samples, which is uniformly diagnosed according to gold standard (www.asd-net.de), data from N= 2613 patients (age 13.3± 10.4, IQ 97,4 ± 20.02) were analyzed, focusing on sensitivity and specificity values of the diagnostic algorithms (ADOS und ADI-R). Due to the huge sample size, an additional sample was generated, which was matched according to gender, diagnosis, the applied ADOS module, age and intelligence (resulting in 454 pairs). We determined items for both genders, which differentiate best between groups (ASD vs Non-ASD) via discrimination analysis.

Results: Comparisons across the whole sample resulted in the following pattern: females with ASD are significantly older than males with ASD, at the time of diagnosis. We observed no IQ differences between both gender groups. Differences according to the intensity of the ASD symptoms were solely observed for older patients (module 3 and 4): female participants show reduced impairments with respect to domains, which are relevant for diagnosis. This effect was especially pronounced during the application of module 3 with moderate effect size. But in the exactly matched sample no differences concerning intensity of symptoms were found between female and male ASD participants. Sensitivity measures of the ADOS cut-off values are reduced in female as compared to male patients, while specificity values are increased. Discriminant analyses show further that there are items like for example, eye contact, which discriminate between ASD and non-ASD independently of gender, while other items discriminate between ASD and non ASD as well, but are dependent on gender.

Conclusions: Interestingly, gender has no influence on specific domains of ASD, when patients are matched, suggesting that gender-depending differences on the ASD symptom-level may be rather attributed to age- and development-related factors and the IQ, than to a specific gender-related phenotype.

96 **183.096** The Stanford Social Motivation Scale: Preliminary Support for a Measure of Social Motivation in ASD

R. K. Schuck[1], *S. Schapp*[2], *E. Solomon*[2], *E. E. Salzman*[3], *L. Allerhand*[2], *R. Libove*[1], *T. W. Frazier*[4], *A. Y. Hardan*[1] *and J. M. Phillips*[1], *(1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)PGSP-Stanford Psy.D. Consortium, Stanford, CA, (3)Psychiatry, UCSF, San Francisco, CA, (4)Autism Speaks, New York, NY*

Background: It has been hypothesized that deficits in social motivation may play a significant contributory role in the social deficits of individuals with autism spectrum disorder (ASD; Dawson et al., 1998; Grelotti et al., 2002; Chevallier et al., 2012). Though some measures assess social motivation as a component of social functioning (such as the Social Responsiveness Scale [SRS-2; Constantino & Gruber, 2005] and Multidimensional Social Competence Scale [Yager & Iarocci, 2013]), there is currently no tool available to specifically measure the drive to engage socially.

Objectives: The current study aimed to create a valid measure of social motivation for individuals with ASD.

Methods: After extensive literature review and consultation with experts in the field, a 71-item questionnaire, the Stanford Social Motivation Scale (SSMS) was developed. The questionnaire includes four content areas derived from theoretical models of social domains: social drive, quality of overtures, behaviors that sustain an interaction, and social recognition. A 28-item subset was identified by experts as being extremely relevant to social motivation. The questionnaire was given to parents of children with ASD and typically developing (TD) controls to determine the validity of the measure. Other measures that included questions about social functioning, such as the SRS, were also collected in order to compare parents' responses with the SSMS.

Results: To date, data have been collected from parents of 62 children with ASD and 14 TD controls. The majority of both groups were male and either Caucasian or Asian. There was a significant difference between the mean SSMS score between the ASD and TD groups ($p < .001$) for both the full 71-item scale and the 28-item scale. There was no significant difference in SSMS performance based on either IQ or age, suggesting that the measured behavior is independent of age or level of cognitive functioning. The 71-item scale was correlated with the 28-item SSMS ($r = .942$, $p <.001$), as well as each of the four content areas (range $r = .997$ to $.563$, $p <.001$). Amongst content scales, strong correlations were found between the 28-item scale and the social drive and behaviors that sustain an interaction scales ($r = .997$; $r = .818$). Moderate correlations were found for the quality of social interactions and social recognition scales ($r = .688$; $r = .563$). The total SSMS score was also highly correlated with the SRS-2 total T-score ($r = .836$; $p <.001$).

Conclusions: Preliminary findings show support for the SSMS as a valid means of characterizing social motivation in children with ASD. It also has the potential to provide a useful tool for measuring this construct across diagnoses, and has implications for phenotyping, treatment planning, and progress monitoring. Further psychometric analysis is currently underway, including the addition of psychiatric and developmental disability comparison groups, as well as a larger sample.

97 **183.097** The Utility of Parent Completed Questionnaires in Age-Specific Protocols Designed to Identify Children at Risk for Autism Spectrum Disorders at an Early Age

N. Chericoni[1], *V. Costanzo*[1], *R. Lasala*[2], *M. L. Scattoni*[3], *F. Apicella*[1] *and F. Muratori*[4], *(1)IRCCS Fondazione Stella Maris, Calambrone (Pisa), Italy, (2)IRCCS Fondazione Stella Maris, Calambrone, Italy, (3)Research Coordination and Support Service, Istituto Superiore di Sanità, Rome, Italy, (4)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy*

Background: Despite increased awareness, many children are still not diagnosed with Autism Spectrum Disorders (ASD) until they are four or older, when the syndrome has been clearly established. Since early intervention has been proved to alter the course of symptoms and the severity of the disorder, numerous lines of research have been focusing on ways to anticipate the age of diagnosis. As the diagnosis of autism is currently based on the observation of the child's behaviour, the development of age-specific protocols for early diagnosis might help clinicians in the process of identifying children at risk for ASD at an earlier age.
Objectives: This study investigated the utility of parent completed questionnaires in identifying toddlers at risk for ASD, as part of a larger ongoing project on the validation of age-specific protocols, specifically designed to identify and diagnose children with ASD at an early age.

Methods: Three groups of children were enrolled in this study and followed longitudinally from 12 to 24 months of age: 30 siblings of children with a diagnosis of ASD; 30 clinically referred children, who were receiving medical attention at a local hospital; 30 typically developing children recruited at local kindergartens. Parents of all three groups were administered a set of age-specific questionnaires (FYI, ITSEA, QUIT, PSI, EMQ, CDI, QBUL, M-CHAT, CBCL, SCQ, RBS-R, Sensory Profile), and children underwent clinical assessment with the Autism Diagnostic Observation Schedule –ADOS and the Griffiths Developmental Scales – GMDS-ER. Parent ratings across groups were compared using an ANOVA with Bonferroni's post hoc tests, and correlation and regression analyses were performed to evaluate to what extent they predicted diagnostic outcome.

Results: The analyses that have been performed so far indicate that some questionnaires might be particularly helpful in clinical decision-making. For example, the Competence domain of the ITSEA at 12 months significantly differentiated all three groups ($p \leq .01$) and significantly correlated with clinical outcomes ($p \leq .05$), with higher scores being more frequently associated with lower cognitive functioning and higher scores on the ADOS at 24 months. The Withdrawn scale of the CBCL at 18 months significantly differentiated siblings with an ASD outcome both from typically developing toddlers and siblings with a familial risk but no ASD outcome ($p \leq .05$). Regression analysis showed that higher scores on the Withdrawn scale predicted an outcome of ASD ($p \leq .003$).

Conclusions: These preliminary results suggest that some subscales of broadband questionnaires investigating the acquisition of interpersonal and social-communication competences may be used in clinical practice to guide clinicians in the challenging task of performing an early diagnosis of ASD. This result appears consistent with findings from previous studies, which show that between 12 and 24 months red flags should be looked for in gaps in the acquisition of normal evolutionary skills, rather than in the presence of specific behavioural symptoms.

98 **183.098** Unseen, but in Plain Sight: Looking Beyond the Camouflage in Women Challenged By Social Interactions, Regardless of Autism Diagnosis

J. S. Beck[1], *R. A. Lundwall*[2], *T. P. Gabrielsen*[3], *J. Cox*[4], *E. I. Anderberg*[1], *S. Kamhout*[1], *A. M. Dixon*[1], *K. Christensen*[1], *L. Peacock*[1], *M. Ekins*[1] *and M. South*[2], *(1)Psychology, Brigham Young University, Provo, UT, (2)Psychology & Neuroscience, Brigham Young University, Provo, UT, (3)Counseling & Special Education, Brigham Young University, Provo, UT, (4)Counseling and Career Center, Brigham Young University, Provo, UT*

Background: There is increasing recognition that girls and women with autism do not fit standard symptom profiles and may be overlooked for diagnosis or misdiagnosed. Some women may consciously "camouflage" their impairments in order to appear more capable during social interactions and during formal assessments such as administration of the ADOS-2. Nonetheless, many of these women, including those with an ASD diagnosis as well as those in diagnostic "gray zones," experience a variety of clinical concerns (e.g., failure to make friends and severe levels of anxiety) that lead to substantial distress and impairment in everyday life.
Objectives: We aimed to capture broad measures of social, emotional, and adaptive function in order to more deeply profile strengths and difficulties of women who find social situations challenging and distressing, who may be confused, anxious, or exhausted by social situations. Alongside standard measures such as the ADOS-2, SRS-2, and BAPQ we developed a rich battery of emotional, developmental, behavioral and interview measures administered to women and to their parents. Our goal is to inform clinical diagnosis including usual diagnostic tools and beyond.

Methods: Initial recruitment through university counseling centers, private practices, and social media identified 55 women who report symptoms associated with ASD per elevated scores (>3) on the BAPQ screening. About half of participants had an existing ASD diagnosis (diagnosed at age 3 to 35 years). Self-report questionnaires included multiple measures of social and emotional function (SRS-2, DASS-21, TSCS-2, Suicidal Behaviors Questionnaire, Gender Group Identification Scale, extensive developmental history) and additional questionnaires for parents. A subset of women (n=24) completed in-person follow-up interviews, ADOS-2, and an objective video-based measure of social cognition (TASIT-S).

Results: Preliminary analyses show extensive levels of distress across all areas of function, independent of previous diagnosis and with little convergence of ADOS scores. The sample shows consistently elevated scores for anxiety, depression and stress, with about 1/3 of the sample falling into the "severe" range. Self-concepts scores almost universally fall into the range of extreme concern, below the 3rd percentile, and there is frequent uncertainty around gender issues. We are currently analyzing qualitative interview data. For example, the comments of one undiagnosed participant described that she has no friends, despite constantly "filtering my quirks to fit in" and repeatedly engaging in a "three-step process" she believes is a failsafe formula for friendship. Questionnaire data from her mother confirmed chronic social difficulties as well as unusual interests and rigidity. Taken together, her symptoms are consistent with a diagnosis of ASD, yet she scored well below diagnostic cut-offs on the ADOS-2.

Conclusions: Beyond short-term, structured tools, multi-informant and multi-measure approaches that assess for social and emotional difficulties may be essential for assessing women for ASD, especially when there is evidence for conscious "camouflaging." Many women with clinically-significant symptoms of ASD may not manifest them during the ADOS-2 or other structured contexts. Given the severity of internalizing disorders in this population, the need for accurate assessment and subsequent informed intervention is urgent.

99 **183.099** Utility and Feasibility of Using the Autism Symptom Interview: A Replication Study.

S. Guttentag[1], *S. Bishop*[2], *R. Doggett*[1], *R. Shalev*[3], *M. Cohen*[4], *C. Lord*[5] *and A. Di Martino*[6], *(1)NYU Child Study Center, New York, NY, (2)University of California San Francisco, San Francisco, CA, (3)Child Study Center at NYU Langone Health, New York, NY, (4)Weill Cornell Medicine, White Plains, NY, (5)University of California Los Angeles, Los Angeles, CA, (6)The Child Mind Institute, New York, NY*

Background: The Autism Symptom Interview (ASI) school-age was developed as a brief phone parent interview about current ASD symptoms to facilitate recruitment and characterization of large-scale research samples. Its first validation study showed that the ASI distinguishes verbal children with ASD from those with other neurodevelopmental disorders with high sensitivity (0.82) and low specificity (0.62). The latter increased to 0.92 when combined with the Autism Diagnostic Observation Schedule-Second Edition (ADOS-2) (Bishop et al., 2017).
Objectives: We aimed to examine 1) the ASI feasibility in the context of an ongoing neuroimaging study, 2) its ability to distinguish those with ASD from those without, and 3) the individual variables that contribute to ASI elevated scores.

Methods: One clinician administered the ASI during an in-person interview, followed by a thorough developmental and psychiatric history. This was paralleled by a child assessment including an ADOS-2 and IQ testing conducted by an independent evaluator. The parent interviewer had knowledge of previous diagnoses/concerns, the child evaluator was “blind” to prior history/concerns. Following assessment/scoring, these independent evaluators discussed their observations and clinical impressions to reach a diagnostic consensus based on DSM-5 criteria. We examined data from 76 verbal children between the ages of 5.5 to 11.9 years (M=8.4±1.7) enrolled in an ongoing study. ASI sensitivity and specificity were assessed, both alone and in conjunction with the ADOS-2. Parent ratings on core ASD and associated symptoms were used to compare groups defined based on diagnostic consensus as well as on those based on the ASI total diagnostic cutoff score.

Results: Per diagnostic consensus, of the 76 children, n=36 were classified as ASD and n=40 as non-ASD, while n=42 met diagnostic criteria on the ASI (ASI+). The ASI distinguished children with ASD from non-ASD with relatively high sensitivity (0.78) and moderate specificity (0.67). When used with the ADOS-2, specificity increased to 0.85. As expected, on average the ASD group had higher ASI total scores than the non-ASD group, as well as elevated ADOS-2 scores and other parent ratings of ASD core symptoms. The diagnostic groups did not differ in parent ratings of associated psychopathology indexed by the Child Behavior Checklist (CBCL). Notably, dividing the children in those with and without elevated ASI scores, regardless of diagnosis (ASI+ and ASI-, respectively), indicated elevated internalizing, externalizing and total CBCL T scores in ASI+ vs ASI- with no differences in ADOS-2 and other ASD core symptom ratings.

Conclusions: Our results suggest the feasibility of administering the ASI in-person in the context of a research study. Our findings are consistent with prior results of ASI moderately high sensitivity and increased specificity when combined with the ADOS-2. Differences in ratings of comorbid psychopathology between groups defined by ASI cutoff, but not in those defined by ASD diagnosis, indicate that comorbid psychopathology may confound results from parent interviews and should be accounted for in the diagnostic process.

100 **183.100** ‘Investigating the Diagnostic Utility of Pathological Demand Avoidance to Better Understand the Educational Experiences of Autistic Children Who Display Extreme Demand Avoidance’.

ABSTRACT WITHDRAWN

Background:
‘Pathological Demand Avoidance’ (PDA) is a term increasingly used by practitioners and parents in the United Kingdom to describe a distinct subgroup of autistic children, who purportedly differ from the typical autistic presentation in their anxiety-driven avoidance of demands. These children are held to warrant distinct educational strategies and supports, yet many educational authorities do not recognise PDA as a diagnostic category. This raises questions about the educational experiences of autistic children who receive this additional diagnosis compared to those who do not. There is, however, a dearth of research on such experiences – and therefore the utility of the PDA diagnosis – in this subgroup of children.

Objectives:

This research sought to: (1) compare directly the educational experiences of autistic children with and without an additional diagnosis of PDA and/or PDA behaviours, and (2) determine the perceived effects of the PDA diagnosis on families’ ability to access appropriate support for their children.

Methods:

216 UK-based parents or carers of autistic children (152 male, 60 female, 4 ‘other’ gender identity - aged between 4 and 19 years) participated in this study. They completed an online questionnaire which included questions about their child’s diagnostic history, measures of their educational experiences (Educational Experiences Questionnaire; Gore-Langton and Frederickson, 2016), in addition to measures of their child’s autistic features (the Social Responsiveness Scale; Constantino, 2005), demand-avoidant behaviours (the Extreme Demand Avoidance Questionnaire (EDA-Q); O’Nions et al., 2014) and behavioural problems (Strengths and Difficulties Questionnaire; Goodman, 1997). Parents were also asked to complete a final, open question inviting them to add any comments about their child’s experience of education.

Results:

To address our aims, participants were divided into three groups, depending on whether their autistic children: (1) had an additional diagnosis of PDA and obtained high scores on the EDA-Q (reflecting elevated PDA behaviours), (2) did not have an additional diagnosis of PDA but obtained high scores on the EDA-Q; and (3) did not have an additional diagnosis of PDA and obtained low scores on the EDA-Q. Higher scores on the EDA-Q were associated with a more negative experience of school. Yet, children who had a formal PDA diagnosis, in addition to their autism diagnosis, reported significantly more negative educational experiences during their child’s most challenging term at school, relative to children with similar EDA-Q scores who did not have an additional diagnosis of PDA.

Conclusions:

These initial findings suggest that a PDA diagnosis is not necessarily supporting children to access positive educational experiences. More in-depth qualitative research is needed to understand why this is the case and whether the diagnostic category has utility for parents and practitioners beyond the context examined in the current study.

102 **183.102** "Evaluation of Support Needs in School Children with ASD in Spain"

P. Jiménez[1], *M. A. Verdugo*[2] *and B. Arias*[3], *(1)INICO.University of Salamanca, Salamanca, Spain, (2)Personality, Assesment and Treatment, INICO. University of Salmanca, SALAMANCA, Spain, (3)Department of Psychology, University of Valladolid (Spain), Valladolid, Spain*

Background:

The constructs about support and support needs have been one of the axes of development in research and implementation of actions aimed at improving the quality of life of people with intellectual or developmental disabilities. Assessing the support needs and the intensity of these supports is a crucial strategy for adults with intellectual disabilities and children in school ages.

Objectives:

The purpose of this research is an evaluation of the support needs and their intensity in children in school ages with Autism Spectrum Disorder (ASD) in Spain, and compared with the intensity of support need showed in other groups with intellectual disability, but without ASD. Besides we wanted to do a first analysis of the support needs in school children with ASD, but without intellectual disability.

Methods:

Management of a support intensity scale (SIS-C) in its first adaptation to the Spanish context. The scale has two sections: (1) exceptional support needs (medical and behavioral) and (2) scale of support needs in representative activities, grouped into seven factors, home life, community life, school participation, school learning, health and safety, social activities and defense or self-representation. The intensity of support is evaluated through three parameters: type of support, frequency of support and daily support time. We evaluated 249 schoolchildren with ASD and intellectual disability, as well as 44 children and adolescents with ASD without intellectual disabilities aged 5 to 16 years. The mean values obtained were compared with a sample of 565 children and adolescents with intellectual disability without ASD from Spain.

Results:

The means obtained showed significant differences in the intensity of support among children and adolescents with intellectual disability without ASD and with ASD; and also when the values of the age groups are contrasted: 5-10 years and 11-16 years. In all the representative activities of the scale, the sample with ASD presents more intense support needs. The sample with ASD without intellectual disability has presented needs of support in diverse areas of support, especially in social activities, defense (self-representation) and school learning.

Conclusions:

The SIS-C scale is a useful tool for assessing support needs in daily life activities in school children with ASD and intellectual disability. The data suggest that the intensity of support needs of students with ASD is greater than that shown by other students with intellectual disabilities who do not have ASD. There are activities in which support intensity is significantly different for the group with ASD, which may be of interest for the processes of: (1) reflection and planning of individual supports, (2) organization of resources and services, and (3) for the development of strategies of educational administration.

103 **183.103** : Investigation of a New Social Communication Observation Schedule for Assessment of Autism Spectrum Disorder (ASD) in Young Children with Profound-Severe Visual Impairment

N. J. Dale[1,2]*, E. Sakkalou*[3]*, S. Glew*[3]*, H. Clarkson*[3]*, M. H. Eriksson*[3]*, D. H. Skuse*[4] *and A. Salt*[5]*, (1)Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom, (2)Clinical Neurosciences, UCL Great Ormond Street Institute of Child Health, London, United Kingdom, (3)UCL Great Ormond Street Institute of Child Health, London, United Kingdom, (4)Behavioural and Brain Sciences Unit, Population Policy and Practice Programme, UCL Great Ormond Street Institute of Child Health, University College London, London, United Kingdom, (5)Great Ormond Street Hospital for Children, London, United Kingdom of Great Britain and Northern Ireland*

Background: Children with congenital profound or severe visual impairment (VI) are at high risk of ASD and social communication difficulties; prevalence of ASD ~30% in several studies. Existing tools used to measure socio-communicative development are highly vision-dependent and not valid for children with VI. A novel visual impairment-social communication observational schedule (VISCOS), drawing on principles of ADOS but specifically designed for 4-7 year olds with profound-severe VI, was developed and initial validation against expert clinician formulation is presented.

Objectives: To investigate the performance of the VISCOS in differentiating children with VI at high risk of ASD and social communication difficulties from those without ASD according to independent expert clinician formulation.

Methods: Preliminary data (45% of planned sample) from forty-five 4-7-years-olds (mean age 5 years 5 months), with congenital disorders of the peripheral visual system with profound VI (PVI, n=7; light perception at best),to severe VI (SVI, n=38, mean 1.00 logMAR).The children engaged in social interaction and play including symbolic play, conversation, auditory story and non-visual theory of mind materials with a trained psychologist assessor, using standard presses designed specifically for children with very low or no vision (VISCOS). Verbal cognition (WPPSI) and vision level (near detection, acuity) were also assessed. The VISCOS assessment was rated by the assessor on the Social Communication difficulties Scale (SCS) and Restricted and repetitive Behaviour Scale (RRBS). A paediatrician with expertise in VI and autism used the video assessments and parent-reported Development and Well-Being Assessment (DAWBA, Goodman et al) to reach a diagnostic formulation (ASD, Social communication difficulties (SCD), Non-ASD) according to DSM-5 criteria.

Results: WPPSI Vocabulary and Information subscales were within the normal range; no significant difference between PVI and SVI subgroup scores. The SCS scores did not differ significantly between PVI and SVI subgroups (U=76.00 p=08), although the scores of the PVI group were more elevated. Negative and stereotyped behaviours (RRBS) were higher in the PVI than SVI group (U=47.50 p=005). The clinician formulation led to 44 children classified as Non ASD (32; 73%), SCD (8; 18%) and ASD (4; 9%). Five out of 7 (71%) children with PVI showed ASD or SCD compared with 9/39 (23%) with SVI. Children rated as ASD or SCD scored significantly higher scores on the SCS (median ASD/ SCD = 14.00; median Non ASD = 6.50; U=44.50, p=.003) and RRBS (median ASD/ SCD = 10.00; median Non ASD = 1.50; U=19.00, p=0001) compared to those with Non ASD. Good sensitivity and specificity was also found (SCS = .70/.71; RRBS = .80/.92 respectively).

Conclusions: This is the most systematic investigation to date developing a new tool for assessing ASD in young children with congenital profound-severe VI. Without involving behaviours or measures that are vision dependent, the new VISCOS showed promising results in relation to identification and diagnosis of ASD or SCD in the context of VI according to expert clinician formulation. Construct validity and the algorithm to identify the most pertinent behaviours related to ASD in young children with VI will also be presented.

104 **183.104** Differences between Multiplex and Simplex Autism: Does Parent Experience Contribute to Differences in Cognitive and Behavioural Development?

D. Berends[1], C. Dissanayake[1] and ***L. P. Lawson***[2,3]*, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, Australia, (3)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia*

Background: It has been suggested that multiplex (MPX) and simplex (SPX) cases of Autism Spectrum Disorder (ASD) may originate from separate genetic aetiologies. Previous research examining differences between these groups has found that MPX children may possess and advantage in cognition and behaviour compared to SPX children suggesting that MPX and SPX groups represent different phenotypes. However, there are a number of limitations within the existing literature. In particular, samples have been biased by the inclusion of singleton children in the SPX group or the recruitment of MPX children from high-risk sibling cohorts, where only the second affected child is included. Further, research has also demonstrated that parental experience and knowledge contributes to improved outcomes for children with ASD. Existing studies examining MPX/SPX differences have not accounted for MPX parent's previous experience with older diagnosed siblings, which may improve outcomes for these second affected MPX probands.

Objectives: The aim in this study was to expand on the literature regarding MPX/SPX differences by not only investigating the possible MPX advantage in a large database sample, but also evaluating if parent experience was a contributor. It was hypothesised that MPX children would demonstrate higher cognitive and adaptive behaviour scores and less ASD symptom severity than SPX counterparts. In addition, it was hypothesised that if parent experience was contributing to the apparent MPX advantage, MPX second affected children would demonstrate better cognitive and adaptive skills, and fewer ASD symptoms compared to their MPX first affected counterparts.

Methods: Four hundred and twenty-nine children from the Autism Genetic Resource Exchange (AGRE) were stratified into first- and second-affected MPX (MPX^1; *n*=152, MPX^2; *n*=143), SPX (*n*=111), and only-child SPX (SPX^{OC}; *n*=23) groups. Group differences were examined using scores from the Stanford-Binet 5th edition, Mullen Scales of Early Learning, Vineland Adaptive Behaviour Scale, and the Autism Diagnostic Observation Schedule. Significant ANCOVA results were followed by post hoc comparisons between groups.

Results: No differences were found between MPX^1 and MPX^2 groups on any of the dependent variables. However, both MPX groups had significantly higher cognitive scores compared to the SPX group. Initially findings showed a significant difference between the MPX and SPX group for adaptive behaviour, such that the MPX group had higher scores compared to the SPX group. However, when cognition was included as a covariate in the analysis the difference was no longer significant. There were no significant differences between the groups on ASD symptom severity.

Conclusions: The current finding of a MPX advantage in cognitive functioning supports the view that MPX and SPX cases may represent different phenotypes of ASD. Further, the null findings between MPX^1 and MPX^2 infer parent experience is less likely to contribute substantially to differences between MPX and SPX groups. Overall, these results suggest that research regarding cognitive functioning in ASD should take into account MPX and SPX status as these groups appear to differ in their cognitive abilities and thus represent separate phenotypes of ASD.

184 - Epidemiology
11:30 AM - 1:30 PM - Hall Grote Zaal

105 **184.105** A Comparison of ASD Screening in Toddlers By Global Developmental Screening and the Modified Checklist for Autism in Toddlers (M-CHAT)

O. Kerub[1]*, E. J. Haas[2], G. Meiri[3,4], N. Davidovitch[5] and I. Menashe[6], (1)Ben-Gurion University, Ministry of Health, Be'er Sheva,, Israel, (2)Ministry of Health, Beer Sheva, Israel, (3)Soroka Medical Center, Beer Sheva, Israel, (4)Soroka Medical Center, Beer Sheba, Israel, (5)Ben Gurion University in the Negev, Beer Sheva, Israel, (6)Public Health Department, Ben-Gurion University, Beer Sheva, Israel*

Background:
Early diagnosis of autism spectrum disorder (ASD) improves long-term outcomes of existing interventions. Systematic screening for early ASD symptoms can considerably reduce the age of diagnosis of the disorder. The most widely used ASD screening tool is the Modified Checklist for Autism in Toddlers (M-CHAT) which has been shown to have high sensitivity and specificity in populations of various ethnic backgrounds.

In Israel, there is no ASD-specific screening program, but rather toddlers undergo serial health visits at government-funded maternal child health centers (MCHCs), which include global developmental screening (GDS) for age appropriate developmental milestones. While GDS may detect a variety of developmental problems, its efficiency in detecting ASD at early ages is unknown.

Objectives: To assess the screening efficiency for ASD of the GDS and M-CHAT among toddlers from an ethnically diverse population in south Israel.

Methods:

We applied both GDS and M-CHAT screening tests to 1,600 toddlers of ages 18-30 months in 35 randomly selected MCHCs in southern Israel. Toddlers who failed in either the M-CHAT or the GDS were referred to child neurologist or child psychiatrist for a more rigorous developmental evaluation based on DSM-5 criteria. In addition, we assessed the current GDS-based referral procedure by asking eleven experienced MCHC nurses to review and provide a referral decision for 200 toddlers based on their full GDS result history.

Results: Of the 1600 toddlers in our study, 84 were referred for further developmental evaluation. Of these, 26 toddlers were identified only by the M-CHAT, 34 only by the GDS, and 24 by both of these tests (Kappa=0.52; p<0.001). Of these, ten toddlers had a confirmed diagnosis of ASD and another 30 toddlers were diagnosed with other forms of developmental delays (DD). Notably, the M-CHAT had a remarkably better sensitivity than the GDS in detecting toddlers with ASD (70.0% vs. 50.0% respectively), and slightly better specificity (98.2% vs. 96.6% respectively). These differences were translated to 2.3 fold difference in positive predictive value (PPV) between these two screening tools. Both methods had an equivalent efficiency in detecting other forms of DD (i.e. sensitivity= 63%; and specificity=98%). There was a remarkable variability between the nurses regarding toddler referral. However, a significant correlation was found between the total number of failed items and the number of referral nurses (Spearman r=0.65; P<0.001) with ≥5 failed items serving as the referral cutoff for the majority (≥6) of the nurses. No association was found between nurses' referral and the age, sex or race of the toddlers.

Conclusions:

Use of the M-CHAT is more effective in detecting children with ASD compared to the GDS approach. Thus, combining these two approaches in the developmental check-up at the MCHCs will improve early detection of ASD and other developmental problems.

184.106 A Population-Based Study of Traffic-Related and Outdoor Air Pollution during Pregnancy and Autism in Denmark

B. Ritz[1]*, Q. Yan*[1]*, Z. Liew*[2]*, X. Cui*[3]*, M. Ketzel*[4] *and O. Raaschou-Nielsen*[5]*, (1)Department of Epidemiology, UCLA Fielding School of Public Health, Los Angeles, CA, (2)Department of Environmental Health Sciences, Yale School of Public Health, New Haven, CT, (3)UCLA Fielding School of Public Health, Los Angeles, CA, (4)Department of Environmental Science, Aarhus University, Roskilde, Denmark, (5)Danish Cancer Society Research Center, Danish Cancer Society, Copenhagen, Denmark*

Background:

A number of previous studies reported that perinatal exposure to air pollutants may increase the risk of autism in offspring. However, most of these studies were conducted in the United States, especially in California. Here we are reporting on the first large European study of autism and traffic related air pollution in Danish children.

Objectives:

Establish the largest nationwide population and record based case-control study of childhood autism and air pollution worldwide, and test the hypothesis that exposure to traffic-related air pollution or PM air pollution is associated with childhood autism.

Methods:

We identified 20,538 autism cases from the National Hospital Registry and the Psychiatric Central Registry among all persons born between 1989 and 2013 in Denmark. For each case, we randomly selected 5 controls without autism matched by birth year and sex. Relying on AirGIS modelling, we estimated outdoor air pollution at the mother's home NOx and particulates – for the 9 months before, during, and after her pregnancy. We calculated odds ratio (OR) and 95% confidence interval (CI), adjusting for birth year, sex, maternal and paternal age, and maternal smoking during pregnancy using conditional logistic regression analysis.

Results:

Using NO2 as a marker of traffic-related air pollution, we estimated an adjusted OR of 1.23 (95% CI: 1.19, 1.26) for autism associated with an inter-quartile-range (IQR) increase in NO2. For an IQR increase in PM2.5 the adjusted OR for autism was 1.13 (95% CI: 1.07, 1.19). Pre and post pregnancy exposure estimates were highly correlated with exposure estimates during pregnancy.

Conclusions:

Our data indicated that exposure to air pollution, especially traffic-related air pollution during pregnancy, is associated with elevated risk of autism in Danish children.

107

184.107 Adapting the Eleat (Early Life Exposure Assessment Tool) to Portugal – a Pilot Study to Tackle Gene-Environment Interactions in Autism Spectrum Disorder

C. Rasga[1]*, J. Santos*[2]*, A. L. Lopes*[3]*, A. R. Marques*[2]*, J. Vilela*[3]*, M. Asif*[4]*, C. K. Walker*[5]*, R. J. Schmidt*[6] *and A. M. Vicente*[7]*, (1)INSA, lisboa, Portugal, (2)INSA, Lisbon, Portugal, (3)BioISI, Lisbon, Portugal, (4)Faculdade de Ciências da Universidade de Lisboa , Lisbon, Portugal, (5)University of California, Sacramento, CA, (6)Public Health Sciences, University of California Davis, Davis, CA, (7)Instituto Nacional Saude Doutor Ricardo Jorge, Lisbon, PORTUGAL*

Background: Genetic factors account for 50 to 80% of Autism Spectrum Disorder (ASD) risk, suggesting that modifiable non-genetic factors may play an important role in ASD. Pre-, peri and post-natal exposure to a variety of environmental factors have previously been implicated in its etiology. However, the comprehensive assessment of environmental exposure in ASD in large datasets from variable environmental settings is still lacking.

Objectives: To examine the role of environmental exposures in a population of Portuguese children with ASD, we translated, adapted and are piloting the Early Life Exposure Assessment Tool (ELEAT).

Methods: The ELEAT was originally developed at the University of California Davis to assess environmental factors in studies of neurodevelopmental disorders. It is a questionnaire completed by mothers of children with ASD, enquiring about Demographic Information, Maternal Conditions/Medical Interventions, Breastfeeding and Child Diet, Maternal Diet, Supplements, Lifestyle, Home and Environment, Environment, Occupation and Exposures. The ELEAT gathers information about environmental exposure along key phases for early neurodevelopment, including 3 months prior to conception, pregnancy, labor and delivery and the first year of life. Given cultural similarities, an ELEAT version adapted to the UK was translated into Portuguese. Cross-cultural problems that might compromise its validity are minimized by European similarities regarding lifestyle, habits, dietary, household and other daily items, comparable access to healthcare and education, as well as employment and infrastructure, and no major cultural adaptations were made. After translation, the ELEAT was piloted in a group of mothers of typically-developing and ASD children, ranging from 1 to 8 years. All mothers had a university degree, and were between 35 and 44 years old. Feedback was obtained from the mothers regarding clarity, length and relevance of the questions, using the inbuilt Evaluation Instrument.

Results: Concerning length, 55% of the mothers considered the ELEAT very long, and 45% considered it slightly long. In a Lickert-type scale, 54% and 36% of the mothers agreed/slightly agreed that the instructions were clear. 36% and 64% agreed/slightly agreed that they were sure about their answers. In four modules (Maternal Condition/Medical Interventions, Breastfeeding, Maternal Diet and Home Environment) between 72% and 91% of the mothers reported high certainty concerning their given answers. Only in Occupation and Exposures did the mothers express lower confidence, with only 36% reporting high certainty. Finally, 64% agreed/slightly agreed that the questions were important, but 27% were neutral. In group discussions similar concerns were reported regarding the length and complexity of the questionnaire, but the main positive conclusions were that the questions were direct and well written.

Conclusions: Integration of the pilot feedback will allow us to enhance the tool for use in Portuguese-speaking communities, improving its capacity to assemble accurate environmental data from diverse cultural settings, and to extend to larger population datasets. Combined with genetic and clinical data, the ELEAT will contribute to the identification of modifiable lifestyle and environmental risk factors for ASD. Such evidence may eventually provide the opportunity for disease prevention or reduced severity by mitigating exposure when genetic susceptibility is identified early in life.

108 **184.108** Exploring Gender Ratio Time Trends in Australian Children with Autism Spectrum Disorder Using Medicare Data

T. May[1] *and K. Williams*[2]*, (1)Deakin University Australia, Burwood, Australia, (2)University of Melbourne and Royal Children's Hospital, Melbourne, Australia*

Background: Many more males are diagnosed with Autism Spectrum Disorder (ASD) than females, with male to female ratios being on average around 4 to 3:1. Some research suggests that milder female cases of ASD have not been identified in the past or are identified later than males. This awareness and the release of the DSM-5 in 2013 acknowledging possible under-diagnosis of females with ASD may have influenced more recent gender ratios. There has also been an increase in ASD prevalence over the last 20 years worldwide. Understanding changes over time in the gender ratio and gender differences in age of diagnosis may inform on various theories relating to why males outnumber females with ASD and the increased prevalence of ASD.

Objectives: This study aimed to use Australian health system Medicare data which captured new ASD diagnoses from 2008-2016 to understand gender trends over time.

Methods: Secondary data analyses from the Australian Medicare system were explored. Two Medicare items that can only be used once when paediatricians/psychiatrists diagnosed a child aged under 13 years with ASD were utilised. Descriptive statistics and regression analyses were used to understand trends over time.

Results: There were a combined total of N=73,463 unique cases identified via the Medicare ASD diagnostic items from 1 July 2008 to 30 June 2016. There were significant increases in new cases of older boys and girls (aged 5-12 years) but not younger children (aged 0-4 years) from 2010/11 through 2015/16. The M:F ratio significantly decreased from 4.1 to 3.0 (p<.001) in this time period in the older children, but the decrease was not statistically significant in younger children (p=.059; 4.2 to 3.5). When using yearly age groups there was a significant decrease in the M:F ratio with increasing age in the years 2014/15 (p=.011) and 2015/16 (p<.001) but no significant decrease in the earlier years (2012/13, 2013/14). Using combined data from 2012/13 to 2015/16, five years of age was the most frequent age of diagnosis for both girls and boys.

Conclusions: Identification of older boys and girls aged 5-12 rather than younger children is contributing to the increased number of ASD cases in Australia. Since 2014 the M:F ratio is decreasing with increasing child age with more older higher functioning females being identified. This could relate to better awareness of milder female cases of ASD following DSM-5 changes which highlight this group. Appropriate services for newly diagnosed primary school aged children should be a focus.

109 **184.109** Classifying Autism Spectrum Disorder By Severity of Functional Limitations: Results from a Large Population-Based Study

M. S. Durkin[1,2]*, M. J. Maenner*[3]*, S. Furnier*[4]*, P. Imm*[5]*, D. Christensen*[3]*, E. Rubenstein*[6] *and N. Dowling*[3]*, (1)Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI, (2)Waisman Center, University of Wisconsin-Madison, Madison, WI, (3)Centers for Disease Control and Prevention, Atlanta, GA, (4)Population Health Sciences, University of Wisconsin-Madison, Madison, WI, (5)University of Wisconsin-Madison, Madison, WI, (6)Waisman Center at UW Madison, Madison, WI*

Background: With the shift to DSM-5 criteria for autism spectrum disorder (ASD) and adoption of the World Health Organization's *International Classification of Functioning, Disability and Health*, there is increased interest in characterizing severity of functional limitations for individuals with ASD and other disabilities. Yet most epidemiologic studies of ASD incorporate little or no information to allow monitoring of the severity of functional limitations of individuals meeting diagnostic criteria for ASD. Adaptive behavior tests, which measure functioning in communication, daily living and motor and social skills, have been shown to be inversely correlated with both the DSM-5 ASD severity categories and the Autism Classification System of Functioning – Social Communication.

Objectives: The aims of this study were to evaluate: (a) the potential to classify ASD cases identified by the Autism and Developmental Disabilities Monitoring (ADDM) Network by severity of functional limitations based on routinely collected adaptive behavior test results; and (b) whether the increase in ASD prevalence among U.S. children between 2000 and 2012 occurred equally across levels of severity of functional limitations.

Methods: We combined cross-sectional data from all ADDM Network sites contributing ASD surveillance data for the period 2000-2012. The ADDM Network is a multiple source surveillance system incorporating health and educational records and clinician reviews to determine the number of 8-year-old children in the population meeting DSM criteria for ASD. Among 22,802 ASD cases, the records of 12,739 (55.9%) included composite and domain scores from one or more adaptive behavior tests. Based on composite score categories from the latest adaptive behavior test administered, we classified cases into three levels of adaptive functioning: (1) no significant limitations; (2) mild limitations; and (3) moderate to profound limitations.

Results: Among 12,739 ASD cases with adaptive behavior information, composite scores indicated no significant functional limitations for 37.1%, mild limitations for 44.2%, and moderate, severe or profound limitations for 18.8%. The percentage classified as having no significant functional limitations increased each surveillance year, from 21.3 in 2000 to 44.5 in 2012, while the percentage with at least moderate functional limitations decreased from, 31.3 in 2000 to 10.6 in 2012 (test for trend p<0.001). Applying the percentages in each functional category to the overall prevalence of ASD, we estimate that the prevalence of ASD per 1,000 8-year-old children with no significant functional limitations increased over time from 1.4 in 2000 to 6.5 in 2012, the prevalence of ASD with mild functional limitations increased from 3.2 in 2000 to 6.6 in 2012, and the prevalence of ASD with moderate to profound functional limitations remained relatively constant over time (2.1 in 2000, 1.6 in 2012). Analyses with imputation of missing data will also be presented.

Conclusions: Tests of adaptive behavior provide an existing source of data for classifying severity of specific functional limitations in epidemiologic studies of ASD. Available data suggest the increase in ASD prevalence between 2000 and 2012 is explained by increases in cases with mild or no significant functional limitations. Additional research could assess limitations not measured by adaptive tests.

110 **184.110** ASD Screening Using Social Communication Questionnaires (SCQ) in 93 Primary Schools in Qatar

F. Alshaban[1]*, E. Fombonne*[2]*, M. Aldosari*[3] *and I. Ghazal*[4]*, (1)Qatar Biomedical Research Institute, Doha, Qatar, (2)Psychiatry, Pediatrics & Behavioral Neurosciences, Oregon Health & Science University, Portland, OR, (3)Center of Pediatric Neurology, Cleveland Clinic Foundation, Cleveland, OH, (4)King Faisal Specialist Hospital and Research Center, Riyadh, SAUDI ARABIA*

Background: There is a scarcity of validated autism screening and diagnostic tools for Arabic-speaking individuals which presents a major challenge to clinicians and researchers in many countries around the world.

Objectives: to evaluate the sensitivity and specificity of the Arabic Version of the Social Communication Questionnaire (SCQ).

Methods: We started by translating the English version of the Social Communication Questionnaire (SCQ) to Arabic language. The back-translation was reviewed by the publisher-assigned reviewer. Then we validated the questionnaires using a sample of 206 ASD cases with 206 age and gender matched controls. The screening cohort are children between the ages 5-12 years attending 93 main stream primary schools in Qatar randomly selected. The Arabic SCQ version sent to be filled by parents.

Results: 9074 SCQ filled, 56% females and 44% males, analysis showed 773 (9%) scored above cut-off (15), 165 (21%) were interviewed, out of which 16 cases were diagnosed with ASD using the ADOS-2 and DSM-5 criteria as a diagnostic tools. while 300 of those who scored below cut-off were interviewed, of which 2 were diagnosed with ASD.

ASD prevalence rate among students between the age 5-12 years attending main stream school found to be 1.4%.

Conclusions: SCQ found to be a reliable screening tool in detecting ASD in general population.

111 **184.111** Assessment of Racial and Ethnic Bias in Autism Spectrum Disorder Prevalence Estimates from a U.S. Surveillance System

P. Imm[1]*, T. C. White*[2] *and M. S. Durkin*[3]*, (1)University of Wisconsin-Madison, Madison, WI, (2)Center for Health and Environmental Data, Colorado Department of Public Health and Environment, Denver, CO, (3)Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI*

Background: The Autism and other Developmental Disabilities Monitoring (ADDM) Network is a multiple-source, population-based, active surveillance system for monitoring Autism Spectrum Disorder (ASD) in the U.S. Children with ASD are included in the surveillance system only if their residence in specific geographic areas can be confirmed in a given surveillance year. Since 2000, the Network has consistently reported disparities in ASD prevalence by race and ethnicity, with the ASD prevalence higher among non-Hispanic white relative to both non-Hispanic black and Hispanic children.

Objectives: The purpose of this study was to assess potential under-ascertainment of ASD in Hispanic and black children due to differential missing information in the surveillance system on residency and race/ethnicity. Two hypotheses tested were: 1) relative to children included in prevalence estimates, those excluded based on inability to confirm residence within the surveillance area were more likely to be black or Hispanic; 2) imputation of missing information on residency and race/ethnicity will result in less racial and ethnic disparity in ASD prevalence than when prevalence estimation is restricted to cases with complete information.

Methods: The Colorado and Wisconsin ADDM Network sites reviewed combined records from Surveillance Years 2012 and 2014. For hypothesis 1, we conducted a case-control analysis to determine whether race/ethnicity of children excluded due to missing residency information (and determined likely to be classified as ASD cases based on a confirmed diagnosis or evaluation/treatment at an Autism Clinic) differed from ASD cases included in the surveillance system. For hypothesis 2, we evaluated the impact on racial and ethnic disparities in ASD prevalence of various approaches to imputation of missing information, such as race/ethnicity imputation based on notes in records, surname data, and/or census block demographics.

Results: Compared to randomly selected ASD cases included in the surveillance system (N=81), those excluded due to missing residency (N=27) were significantly less likely to be white non-Hispanic (48% vs 69%; $p < 0.05$) and more likely to be Hispanic (44% vs 15%; $p < 0.01$). Additionally, inclusion of children with unconfirmed residency and imputation of race/ethnicity information for confirmed cases resulted in slight increases in ASD prevalence overall (from 12.4 to 12.6), but did not affect the ratio of ASD prevalence in white non-Hispanic versus other groups. For example, the ratio of prevalence in white compared to black children was 1.5 (95% CI: 1.25-1.73) in the complete case-only analysis and was unchanged after inclusion of cases with missing residency confirmation and imputed race/ethnicity.

Conclusions: Although potential ASD cases excluded from the surveillance system due to missing residency information were significantly more likely to be from under-represented racial/ethnic groups than the included cases, the strength of this bias and the number of excluded cases were insufficient to account for the observed racial and ethnic disparities in ASD prevalence. This evaluation provides evidence of the robustness of the surveillance system while suggesting the need for continued research into the disparities in ASD prevalence.

112 **184.112** Autism Diagnostic Timeline: No Disparities between Hispanic and Non-Hispanic White Populations in Western New York

J. Herrera[1]*, M. Anto-Ocrah*[2] *and S. Hyman*[1]*, (1)Pediatrics, University of Rochester School of Medicine, Rochester, NY, (2)Public Health Sciences, University of Rochester School of Medicine, Rochester, NY*

Background: Early autism spectrum disorder (ASD) diagnosis and treatment improves developmental outcomes. National data describes disparities between Hispanic and non-Hispanic white (NHW) children regarding access to early intervention (EI) and diagnostic services - Hispanic children are less often evaluated for ASD by age 36 months, and more likely to be diagnosed after age 4 years, than are NHW children. New York State has the fourth largest Hispanic population in the country, yet the northeastern U.S. is underrepresented in national data.

Objectives: Describe ages of entry to EI services, referral, initial evaluation, and first ASD diagnosis according to child's ethnicity/race (Hispanic, NHW) and primary language (English, bilingual English-Spanish, or Spanish) in a northeastern U.S. tertiary care clinic sample. This clinic is the primary source for ASD diagnosis in the western New York region.

Methods: We reviewed 493 medical records of children ages 24-60 months with an ASD diagnosis seen in clinic between September 1, 2015-February 28, 2017. Subjects were selected on the basis of receiving an ASD diagnosis during that time and self-identified ethnicity and race. Exclusion criteria were non-Hispanic race other than white, gestational age <37 weeks, genetic diagnosis with known increased ASD risk, primary language other than English or Spanish, and missing data on variables of interest.

Results: Of 493 patients reviewed, 177 (36%) met criteria and were included in the analyses. Fifteen percent (n=27) identified as Hispanic, 85% (n=150) as NHW. Of Hispanic patients, 63% (n=17) were English-speaking (Hisp-E), 15% (n=4) were bilingual (Hisp-B), and 22% (n=6) were Spanish-speaking (Hisp-S).

Significantly more Hispanic children had public health insurance compared to NHW (70 v. 45%, respectively, p=0.017). Hispanic children were referred for evaluation earlier than NHW (Hispanic 28.62±7.21 v. NHW 32.66±9.77, p=0.045). EI participation rate was similar between groups (Hispanic 85 v. NHW 80%, p=0.549), with no difference by age at entry to EI services (Hispanic 22.23±4.88 v. NHW 22.64±5.84, p=0.756). No differences existed by ages at initial evaluation (Hispanic 36.07±8.22 v. NHW 38.57±9.96, p=0.221) or first ASD diagnosis (Hispanic 36.81±8.53 v. NHW 39.60±10.14, p=0.181). Ages reported in months.

Considering Hispanic language subgroups, there were no statistically significant differences between these and NHW on all outcomes of interest. Although not significant, Hisp-S had highest EI participation (100%), compared to Hisp-E (82%), NHW (80%), and Hisp-B (75%). Hisp-S also had earliest mean ages of referral, evaluation, and diagnosis.

Conclusions: Contrasting with published literature, Hispanic children in this sample participated in EI services at similar rates as NHW patients. They also were evaluated for and diagnosed with ASD on average by age 36 months, comparable to NHW counterparts. Variation from the literature may be due to regional differences in screening, referral, and availability of services, as well as differences in the Hispanic population sampled. Reasons for differences between this sample and national data should be further explored. Higher utilization of public health insurance among Hispanics may have resulted in earlier age of referral for patients in this sample because of mandated developmental screening; barriers preventing their timely evaluation must be considered.

113 **184.113** Autism Prevalence in Union County New Jersey, 2000-2014

J. Shenouda[1] *and W. Zahorodny*[2]*, (1)Pediatrics, Rutgers NJ Medical School, Newark, NJ, (2)Rutgers New Jersey Medical School, Newark, NJ*

Background: Centers for Disease Control and Prevention (CDC) estimates from the most comprehensive Autism surveillance network indicate that Autism Spectrum Disorder (ASD) prevalence rates have increased dramatically since 2000. New Jersey (NJ) had the highest baseline ASD rates among the ADDM sites and showed significantly higher estimates, over all cycles of monitoring. Among the 4 counties constituting the NJ surveillance region, ASD estimates and case characteristics from Union County NJ were based on the most complete access to source information, so we endeavored to understand more about ASD and the increase in prevalence from a consideration of ASD in Union County.
Objectives: To compare ASD prevalence estimates based on the number of children confirmed with ASD by ASD surveillance activities, at age 8 years from 2000 to 2014. To describe the ASD distribution by sex, race/ethnicity, ASD diagnosis age and by severity of ASD (impairment), to specify any disparities, and to evaluate the possibility that increasing ASD prevalence was driven by greater identification of children with mild levels of ASD.

Methods: Standard ADDM case finding, ASD case description and prevalence determination procedures were conducted across 7 cycles of ASD monitoring in all twenty-one municipalities. Population denominators were obtained from CDC's National Center for Health Statistics (NCHS) most recent vintage postcensal bridged-race population estimates. Poisson approximation to the binomial distribution was used to calculate 95% confidence intervals for prevalence rates.

Results: We identified 1,071 ASD cases (8 year-old children) in Union County, NJ, from 2000 to 2014 by consistent population-based monitoring according to the CDC/ADDM method. ASD prevalence increased 130% during that period (12.63 (95%CI: 10.3-15.4) per 1000 8 year-olds to 29.01 (95%CI: 25.4-33.1). Diagnosis of ASD (by community providers) increased by 165% (7.38 (5.6-9.5) to 19.56 (16.6-23)), while Special Education eligibility under the Autism classification increased by 172% (4.56 (3.2-6.3) to 12.41 (10.1-15.2)). Male to Female ratio (5 to 1) was consistent throughout, but the rate of increase was higher among girls. ASD increased significantly across all categories of race/ethnicity and early observed race-based differences in ASD prevalence were not evident in 2014. The median age of ASD diagnosis in 2000 was 53 months (SD 21.2, 19-104), while in 2014, median age of ASD diagnosis was 48 months (SD 22.2, 14-105). When stratified by severity of impairment and intellectual ability, the greatest increase in ASD prevalence was among children with severe impairment, rather than among those with mild ASD. Similarly, ASD prevalence increase was greater among children with cognitive impairment (CI) or borderline CI, than among children with average or above average cognitive functioning.

Conclusions: All NJ indicators of ASD prevalence increased significantly between 2000 and 2014. We did not observe significant improvement in the age of first ASD diagnosis over time or disproportionate increase in the identification of mildly impaired children or children with average or higher cognitive ability, casting doubt on the hypothesis that increasing ASD prevalence was substantially due to factors reflecting better awareness.

114 **184.114** Autism Spectrum Disorder Prevalence in Immigrant Communities in Minnesota

J. Poynter[1]*, E. Hallas-Muchow*[2]*, J. A. Hall-Lande*[3]*, A. N. Esler*[2]*, A. Gulaid*[2] *and A. Hewitt*[4]*, (1)Pediatrics, University of Minnesota, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN, (3)UCEDD, University of MN, Minneapolis, MN, (4)U of MN, Minneapolis, MN*

Background:
Children of immigrants may have higher rates of autism spectrum disorder (ASD) (Crafa and Warfa 2015). This appears to be especially pronounced in children from countries with a low human resource index (Barnevik-Olsson et al. 2008; Keen et al. 2010; Magnusson et al. 2012). In our previous ASD surveillance project in Minneapolis, we compared prevalence of autism in Somali children and children from other racial/ethnic groups ages 7-9 years. We found that Somali and white children had a similar prevalence of ASD, which was higher than that of non-Somali black and Hispanic children (Hewitt et al. 2016). Notably, Somali children with ASD were far more likely to have co-occurring intellectual disability (ID) than children with ASD in other racial/ethnic groups.

Objectives:

In this analysis, we will compare ASD prevalence in 8 year olds across racial/ethnic groups using data from the Minnesota site of the CDC Autism and Developmental Disabilities Monitoring (ADDM) Network, with a particular focus on two large racial/ethnic groups in MN: Somali and Hmong. Minnesota is home to the largest population of Somali immigrants, with an estimated 57,000 Somalis, and the second largest population of Hmong, more than 66,000 (American Community Survey 2015). We will also compare the co-occurrence of ID in children with ASD across racial and ethnic groups.

Methods:

Prevalence calculations will utilize standardized ADDM methods (Christensen et al. 2016; Hewitt et al. 2016) involving systematic record review of health and special education records of 8 year old children within our defined surveillance area. The area includes four school districts in two large urban counties in MN. Population denominators will be obtained from CDC's National Center for Health Statistics vintage 2016 postcensal bridged-race population estimates for 2014 and adjusted to include only children living in the surveillance area. A child is classified as Somali or Hmong based on reported home language in education and health records.

Results:

Prevalence estimates will be compared across racial/ethnic groups assuming a Poisson distribution. Chi squared and Fisher's exact tests will be used to identify differences between populations. We will also compare rates of ASD for children in MN with overall U.S. prevalence reported by the CDC. Finally, we will compare the prevalence of co-occurring ID in children with ASD to compare with previous findings.

Conclusions:

Because ASD early identification can improve outcomes, identifying subgroups of children with a higher prevalence or more severe forms of ASD can help inform public health policy and improve outcomes for individuals with ASD and their families. Differences in prevalence by racial/ethnic group may suggest that culturally sensitive methods for outreach and diagnosis are warranted.

115 **184.115** Autism-Associated DNA Methylation at Birth from Multiple Tissues Is Enriched for Autism Genes in the Early Autism Risk Longitudinal Investigation (EARLI)

K. M. Bakulski[1], *M. D. Fallin*[2], *A. P. Feinberg*[3], *J. I. Feinberg*[2], *I. Hertz-Picciotto*[4], *L. A. Croen*[5], *C. J. Newschaffer*[6], *S. Brown*[3], *J. Dou*[7] *and M. Aung*[7], *(1)University of Michigan, Ann Arbor, MI, (2)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Johns Hopkins University, Baltimore, MD, (4)University of California at Davis, Davis, CA, (5)Division of Research, Kaiser Permanente, Oakland, CA, (6)AJ Drexel Autism Institute, Philadelphia, PA, (7)University of Michigan, School of Public Health, Ann Arbor, MI*

Background: Risk for autism spectrum disorders (ASD) is conferred through genetic and environmental exposures, and emerging evidence suggests DNA methylation is altered in ASD. Few studies have considered prospective designs with DNA methylation measured in multiple tissues.
Objectives: To determine the relationships between DNA methylation in maternal blood, cord blood, and placenta with ASD diagnosis.

Methods: In the Early Autism Risk Longitudinal Investigation (EARLI), an ASD-enriched birth cohort, genome-scale maternal blood (early n=140 and late n=75 pregnancy), infant cord blood (n=141), and placenta (maternal n=106 and fetal n=107 compartments) DNA methylation was assessed on the Illumina 450k HumanMethylation array and compared to ASD diagnosis at 36 months of age. We tested for differences in site-specific and global methylation and for enrichment of single sites for ASD risk genes from the Simons Foundation Autism Research Initiative (SFARI) database.

Results: No individual DNA methylation site was associated at genome-wide significance, however individual DNA methylation sites associated with ASD ($P<0.05$) in each tissue were highly enriched for SFARI genes (cord blood $P = 2.6\text{x}10^{-30}$, maternal blood early pregnancy $P = 1.6\text{x}10^{-29}$, maternal blood late pregnancy $P= 4.1\text{x}10^{-12}$, maternal placenta $P= 2.4\text{x}10^{-27}$, fetal placenta $P=1.2\text{x}10^{-13}$). Analyses of additional behavioral phenotypes will be presented, as well as results for overall (global) methylation comparisons across cord, maternal blood, and placenta.

Conclusions: Across multiple tissues, DNA methylation sites nominally associated with later ASD diagnosis were enriched for ASD risk genes. Our blood and placenta tissue study demonstrates the utility of examining DNA methylation prior to ASD diagnosis.

116 **184.116** Changes in the Prevalence of Autism Spectrum Disorder in Utah: A Cohort Approach

A. V. Bakian[1], *C. A. Palmer*[1], *C. Kingsbury*[2], *N. Taxin*[2], *W. M. McMahon*[1] *and D. A. Bilder*[1], *(1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Bureau of Children with Special Health Care Needs, Utah Department of Health, Salt Lake City, UT*

Background: Accurate autism spectrum disorder (ASD) prevalence estimates are critical for driving policy decisions such as planning for ASD-related services. U.S.-based efforts to identify children with ASD and estimate ASD prevalence often use cross-sectional study designs that are limited to a specific age (e.g. age 8). Recent research suggests that approximately 1/3 of children with ASD are not identified until after age eight. Delayed identification may be related to ASD severity, race/ethnicity and/or socioeconomic status. Hence, some prevalence estimates may be overly-conservative and biased. A cohort study design in which children from specific birth cohorts are ascertained for ASD at different ages may yield more accurate and unbiased ASD prevalence estimates.
Objectives: 1) Estimate ASD prevalence bi-annually in the 1994 birth cohort in Utah starting at age 8 through age 16, and 2) compare ASD prevalence across study years.

Methods: Data for this study was acquired from the Utah Registry of Autism and Developmental Disabilities (URADD), a passive, population-based ASD surveillance system. Children born in 1994 in a four county (Davis, Salt Lake, Utah and Tooele) Utah surveillance region were ascertained biannually for ASD starting at age 8 through age 16 based on a community medical ASD diagnosis and/or autism special education eligibility. Overall ASD prevalence and ASD prevalence by gender were estimated in surveillance years (SY) 2002, 2004, 2006, 2008, and 2010; the adjusted Wald method based on a normal approximation was used to estimate 95% confidence intervals. Chi-square tests were used to compare the prevalence of ASD across years.

Results: 159 and 557 children from the 1994 birth cohort were identified with ASD at age 8 (SY2002) and age 16 (SY2010), respectively. The female to male ratio was 1:6 in SY2002 and 1:4 in SY2010. ASD prevalence increased 237% between SY2002 (age 8) and SY2010 (age 16) and was 6.1/1000 8-year-old children in SY2002 and 18.8/1000 16-year-old children in 2010 (Figure). In comparison, the prevalence of ASD among 8-year-old children in SY2010 was 19% lower (prevalence =15.8/1000; 95% confidence interval (CI): 14.5-17.1; p = 0.004) than that of 16-year-olds. The odds of being identified with ASD was three times greater among 16-year-olds compared to 8-year-olds from the 1994 birth cohort (Odds ratio: 3.14; 95% CI: 2.63-3.74; p<0.0001).

Conclusions: Utah's ASD prevalence increased significantly between SY2002 and SY2010 within the 1994 birth cohort. The current study demonstrates that ASD prevalence continues to increase following early childhood and well into adolescence. This pattern may be the result of multiple factors including improved ASD awareness, recognition, referral and access to services. Further research is needed to identify the specific drivers of within cohort increases in prevalence. ASD prevalence among 8-year-old children in Utah is a conservative estimate; policy makers should consider basing decisions on prevalence estimates that incorporate a wider age range including adolescents.

117 **184.117** Demographic, Diagnostic, and Clinical Characteristics of Adult Participants in the SPARK ASD Cohort

***H. Zaydens**, L. A. Green Snyder, A. Daniels, P. Feliciano and W. K. Chung, Simons Foundation, New York, NY*

Background:

It is well recognized that there is a dearth of research on adults with Autism Spectrum Disorders (ASD) in the United States[1]. The absence of research not only impedes our ability to understand causes of ASD[2], but also limits the development of adequate supports and services for the adult ASD community[3]. Due to the heterogeneity of ASD, large numbers of individuals are needed in research, including adults for whom challenges differ[4].

Objectives:

The aim of the current study is to summarize the characteristics of adults with ASD in the SPARK cohort.

Methods:

From December 2015 through October 1, 2017, ASD adults enrolled online at sparkforautism.org, completed brief medical history and demographic surveys. Adults included dependents enrolled by their legal guardians and independent adults, many of whom are parents themselves. Data analyses, including measures of central tendency (means) and proportions, were performed using Stata, version 12.0.

Results:

During the study period, SPARK enrolled a total of 2,787 adults, of whom 1,654 were registered by a legal guardian and 1,133 are legally independent. Almost 80% of the registered dependent adults are male, as compared to 54% of the independent adults. The mean age at diagnosis was 6 years (SD 5.3) for dependent adults and 20.5 years (SD 16.8) for independent adults. Twenty-four (24) and 19 percent of dependent and independent adults, respectively, have neurological conditions; 11% of dependent adults reported seizure disorder or epilepsy as compared to 4% of independent adults. With regard to psychiatric and developmental conditions, 52% of dependent adults and 70% of independent adults, respectively, reported having anxiety disorder, obsessive-compulsive disorder or mood disorders including depression. Sixty-three percent of dependent adults as compared to 15% of independent adults reported having developmental, language or learning disorder. Ninety-one (91) percent of dependent adults as compared to 42% of independent adults reported having IEPs for autism services; 88% of dependent adults versus 54% of independent adults reported using ASD therapies.

Conclusions:

Data collected from adult participants in SPARK indicate a high frequency of psychiatric co-morbidities in both dependent and independent adults, particularly mood and anxiety disorders. Although dependent adults are expected to have more severe challenges, independent adults showed a similar, high rate of co-morbid neurological disorders. At the same time, far fewer independent adults received proper diagnosis or services for ASD in their childhood[3]. Ultimately, these findings underscore the importance of continued, longitudinal research in adults with ASD as a way of better understanding the life course of the condition and to develop better services and systems of support.

118 **184.118** Does Maternal Prescription Opioid Use during Pregnancy Increase a Child’s Risk of ASD or Developmental Disability?

***E. Rubenstein**[1], J. C. Young[2], L. A. Croen[3], C. DiGuiseppi[4], N. Dowling[5], L. C. Lee[6], L. Schieve[5], L. Wiggins[5] and J. Daniels[7], (1)Waisman Center at UW Madison, Madison, WI, (2)Epidemiology, University of North Carolina, Chapel Hill, NC, (3)Division of Research, Kaiser Permanente, Oakland, CA, (4)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (5)Centers for Disease Control and Prevention, Atlanta, GA, (6)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (7)University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Opioid use among pregnant women has increased along with the stark rise in US opioid prescribing rates from 1999 to 2015. While opioid use during pregnancy has been associated with poor pregnancy outcomes, including neonatal abstinence syndrome, preterm birth and some congenital malformations, little is known about maternal opioid use during pregnancy and the child’s risk of neurodevelopmental conditions, such as autism spectrum disorder (ASD) or non-ASD developmental disability (DD).

Objectives: Examine associations between maternal prescription opioid use during pregnancy (from three months preconception to delivery), and ASD, DD without ASD features, or autism traits (either ASD or DD with ASD features) in children enrolled in the Study to Explore Early Development (SEED).

Methods:

: SEED is a multi-site case-control study of ASD risk factors and phenotype in children aged 3-5 years, from 2003 to 2011. Children with ASD or other DDs were identified from schools and healthcare providers. Population controls (POP) were randomly sampled from birth certificates at each site. ASD case status was confirmed with a developmental evaluation that included the Autism Diagnostic Interview-Revised and Autism Diagnostic Observation Schedule. Children receiving the ASD evaluation but not meeting SEED criteria for ASD were identified as having DD with ASD features. Children with DD diagnoses who did not have a SEED ASD evaluation were considered to have DD without ASD features. To evaluate autism traits independent of meeting a diagnostic threshold for ASD, we combined the ASD and the DD with ASD features groups. Maternal prescription opioid use and timing of use were determined by prescriptions abstracted from maternal prenatal care medical records. Study children included 1369 with ASD, 1414 with other DDs (938 without ASD features), and 1577 POP. We calculated odds ratios (ORs) using logistic regression adjusted for confounders affecting estimated ORs by >10% (maternal race/ethnicity, maternal education, smoking, depression, and study year) comparing cases (ASD, DD without ASD features, autism traits) to POP by prescription opioid exposure (any use, use in three months preconception, by trimester).

Results:

Overall, mothers of 7.7% (N=336) of study children were given prescription opioids just before or during pregnancy. In unadjusted analyses, prescription opioid use, preconception or during pregnancy, was associated with ASD (OR 1.56, 95% confidence interval [CI]: 1.19, 2.06) and autism features (OR: 1.61, CI: 1.24, 2.08), driven largely by exposure prior to and during the first trimester. After adjustment, ORs for use during any period were attenuated for the ASD (OR: 1.27, CI: 0.95, 1.69) and autism features (OR: 1.31, CI: 1.00, 1.72) groups. In all groups, adjusted ORs for prescription opioid use preconception were greater than 1.95 but only statistically significant for the autism features group (OR: 2.58, CI: 1.08, 6.16).

Conclusions: Maternal prescription opioid use just before or early in pregnancy led to increased odds of ASD, a statistically significant association with autism features, and no association with DD without ASD features. Findings may suggest etiologic pathways involving placental or fetal exposure that lead to ASD and DD, but may also be attributable to unmeasured or residual confounding.

119 **184.119** Advanced Maternal Age Is Not Independently Associated with Age at First Evaluation That Notes Autism Traits Among Children with ASD.

E. Rubenstein[1]*, M. S. Durkin*[2]*, R. A. Harrington*[3]*, R. S. S. Kirby*[4]*, L. Schieve*[5] *and J. Daniels*[6]*, (1)Waisman Center at UW Madison, Madison, WI, (2)Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI, (3)Johns Hopkins University, Baltimore, MD, (4)Community and Family Health, University of South Florida, Tampa, FL, (5)Centers for Disease Control and Prevention, Atlanta, GA, (6)University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background:
Advanced maternal age (AMA), defined as childbirth at 35 years or older, is a well-known risk factor for poor pregnancy and child health outcomes, including increased risk of autism spectrum disorder (ASD). Many mothers of AMA are aware of their higher risk for suboptimal pregnancy outcomes compared to younger mothers. Whether this awareness results in earlier age at identification of ASD in children of AMA mothers has not been studied.

Objectives: Our objective was to estimate effects of AMA on timing of the child's first evaluation that notes ASD traits using data from the Autism and Developmental Disabilities Monitoring (ADDM) Network, independent of confounding socio-economic factors.

Methods: The ADDM network systematically collects data to determine ASD prevalence among 8-year-old children in multiple sites across the United States. The active surveillance process involves review of medical and health records against a standardized ASD case definition by trained experts. We utilized data on ASD cases with available birth certificate data from surveillance years 2008, 2010, and 2012. Age at first evaluation that noted autism traits was determined by systematic record review of all child evaluations, looking for trigger words that indicated ASD. Linear regression and Cox proportional hazard models were adjusted for maternal education, race/ethnicity, prior live births, study site, and child year of birth. We additionally stratified by intellectual disability (ID) status.

Results: Over the three surveillance years, 10,358 children met surveillance criteria for ASD and had maternal age data from the birth certificate, of which 19.7% had mothers of AMA. These mothers had higher levels of education, more prior live births, and older age of the child's father at childbirth than non-AMA mothers. In crude analyses, children with AMA mothers had an earlier first evaluation that noted ASD traits (41.3 months compared to 46.5 months, mean difference -2.43 months, 95% Confidence Interval [CI]: -3.43, -1.43) with significantly different distributions (Hazard ratio [HR]: 1.12, 95% CI: 1.06, 1.18). However, after adjusting for maternal education, race and other covariates, these associations were attenuated (mean difference -0.11 months, 95% CI: -1.24, 1.03, HR 1.02, 95% CI: 0.96, 1.10). When stratifying by child ID status, age at first evaluation that noted ASD traits was later for those without ID, but there were no significant difference by AMA status in either ID stratum (Mean difference with ID: 0.11, 95% CI: -1.73, 1.93; without ID: -0.03, 95% CI: -1.68, 1.61).

Conclusions: AMA was not associated with earlier age at first evaluation that noted ASD traits after adjustment for confounders. Older maternal age may act as a proxy for greater educational achievement, socio-economic status, and having had more children, all of which are associated with younger age at child's first evaluation. It is important to target early evaluations and screenings to children at high risk of ASD from lower socio-economic demographics to improve age at diagnosis.

120 **184.120** Green Space Exposure Predicts Anxiety and Conduct Problems in Youth with ASD

B. Barger[1]*, L. Larson*[2]*, S. Ogletree*[3]*,* ***D. Roberts***[4]*, J. Torquati*[5]*, S. Rosenberg*[6]*, C. Johnson-Gaither*[7]*, J. M. Bartz*[8]*, E. Moody*[9]*, A. Gardner*[10] *and A. Schutte*[11]*, (1)Georgia State University, Atlanta, GA, (2)LRLarson@ncsu.edu, NC State, Raleigh, NC, (3)Parks, Recreation, and Tourism Management, Clemson University, Clemson, SC, (4)GA State University, Atlanta, GA, (5)U of Nebraska, Lincoln, NE, (6)University of Colorado Anschutz Medical Campus, Aurora, CO, (7)USDA Forest Service, Southern Research Station, Athens, GA, (8)Educational Specialities, Northern Arizona University, Flagstaff, AZ, (9)University of Colorado, Denver, Aurora, CO, (10)U. of Arizona, Tuscon, AZ, (11)U. of Nebraska, Lincoln, NE*

Background:
Exposure to green space confers an array of physical, mental, and health benefits. However, most studies examining relationships between green space, health, and well-being focus on adults, typically developing children, and children with ADHD. Currently, there is no research on the effects of green space on the mental health and behavior of youth with autism spectrum disorders (ASD).

Objectives:

We sought to determine whether green space exposure predicts decreases in the severity of co-morbid anxiety symptoms in children with ASD. We hypothesized that anxiety and conduct problems symptoms would be less severe for youth in settings dominated by "gray" space (e.g., roads, buildings) (H1) and less severe for youth in settings characterized by higher green space (H2).

Methods:

We used national Zip-code level data from the National Survey of Children's Health (NSCH, 2012) and the National Land Cover Database (NLCD) to investigate connections between proximity to green space, gray space, and severity of anxiety and conduct problems (low versus moderate to high), in youth diagnosed with ASD) (n=1284). All analyses include weighted and stratified binary logistic regression models. Respectively, green space and grey space were quantified as the percentage of the tree canopy coverage and built environment at the Zip-code level; the NLCD and NSCH were merged and analyzed on-site at the Centers for Disease Control in Atlanta. All models statistically controlled for the following variables: Severity (low/moderate-high) of co- morbid intellectual disability, learning disability, attention deficit disorder, and autism symptoms; gender; federal poverty level; age bracket (early childhood, middle childhood, and adolescence); race/ethnicity (White, Black, Hispanic, Other); maternal education; insurance status (private, public, and none); and English Language status (English speaking, non-English speaking).

Results:

Results of the logistic regression models supported small effects of environmental variables on anxiety and conduct problem severity. Impervious surface (aOR = 1.03, $p < .05$) and tree canopy (aOR = 1.03, $p < .05$) significantly predicted higher odds of moderate to high levels of anxiety problems in youth with ASD, supporting H1 but refuting H2. Furthermore, tree canopy coverage was associated slightly lower odds of moderate to severe conduct problems (aOR = 0.98, $p < .05$), supporting H1; grey space was not associated with conduct problem severity refuting H2.

Conclusions:

Our study, the first of its kind to examine the relationship between nature exposure and anxiety and conduct problems in youth with ASD. Both impervious surface coverage and tree canopy coverage increased the risk of severe anxiety in youth with autism, who might experience the stress-reducing benefits of nature differently than their typically developing peers. Furthermore, proximity to green space predicted slightly lower odds of conduct problems. This analysis is limited primarily by its reliance on zip code level environmental variables and rough parent report estimates of anxiety and conduct problem severity. More research using objective diagnostic metrics at finer spatial scales would help to illuminate complex relationships between green space, anxiety, and conduct problems in youth with ASD.

121 **184.121** Incomplete Vaccination and Risk of Autism Spectrum Disorder

B. Kim[1]*, M. Ha*[2,3]*, Y. S. Kim*[4]*, Y. J. Koh*[5]*, H. J. Kwon*[2,3]*, M. H. Lim*[3,6]*, K. C. Paik*[3,7]*, P. S. Hong*[8] *and B. L. Leventhal*[4]*, (1)University of California, San Francisco (UCSF), San Francisco, CA, (2)Department of Preventive Medicine, Dankook University College of Medicine, Cheonan, Korea, Republic of (South), (3)Environmental Health Center, Dankook University Medical Center, Cheonan, Korea, Republic of (South), (4)University of California San Francisco, San Francisco, CA, (5)5The Korea Institute for Children's Social Development, Rudolph Child Research Center, Seoul, Korea, Republic of (South), (6)Psychology, Dankook University College of Public Services, Cheonan, Korea, Republic of (South), (7)Psychiatry, Dankook University College of Medicine, Cheonan, Korea, Republic of (South), (8)PSYCHIATRY, UCSF, San Francisco, CA*

Background: The recent decline in childhood vaccination has resulted in outbreaks of infectious diseases with public health and economic consequences in the US. Such vaccine hesitancy partly stems from parental fear that vaccines increase risk for Autism Spectrum Disorder (ASD).
Objectives: We examined the relationship between completion of 6 types of vaccinations in childhood and higher risk for ASD, using an internal replication design.

Methods: Two large South Korean epidemiologic samples were used to: 1) Generate hypotheses about completion of all 6 types of vaccination and increased risk for ASD in a Discovery Sample (DS: N=10,006); and, 2) Replicate the initial findings in a Replication Sample (RS: N=29,381). Mothers reported completion of 6 types of vaccination, including BCG, HepB, MMR, JEV (Japanese Encephalitis Vaccination), DTaP and Polio. Completion of the vaccinations were categorized into three groups: <3 , 4-5 , and 6 vaccines. Three levels of risks for ASD diagnosis was estimated with the Autism Spectrum Screening Questionnaire(ASSQ): low (ASSQ<10), intermediate (ASSQ=10-14), and high (ASSQ≥15) risk. Multivariate ordinal regression was performed: model 1 controlled for demographic factors and model 2 controlled for demographic and confounders (family history of psychiatric disorders, prematurity, and birth order).

Results: 84.3 % of DS and 80.1% of RS were fully vaccinated. After adjusting for demographic covariates and confounders, children who were vaccinated incompletely were at increased ASD risk when compared to those fully vaccinated in the DS (adjusted odds ratio [aOR] = 2.33, 95% CI, 1.53-3.56 in vaccination less than 3; aOR=1.42, 95% CI, 1.17-1.73 in 4-5 vaccination). This initial finding was replicated in the RS (aOR=2.19, 95% CI, 1.80-2.67 in vaccination less than 3; aOR=1.44, 95% CI, 1.32-1.58 in 4-5 vaccination).

Conclusions: Our data suggest that vaccination does not increase risk for ASD but may carry protective effects against ASD. Vaccination has proven to be a successful and effective public health strategy to prevent life-threatening infectious disease in childhood, and to improve the well-being and health of children. When replicated in other populations, the benefit of vaccination might extend to its protective effect for common childhood neurodevelopmental disorders, like ASD.

122 **184.122** Infection and Fever during Pregnancy and Risk for Autism: A Systematic Review and Meta-Analysis

A. Silberman[1]*,* ***N. Tioleco***[1]*, K. Stratigos*[1]*, S. Banerjee-Basu*[2]*, M. Spann*[1]*, A. Whitaker*[1] *and J. B. Turner*[1]*, (1)Department of Psychiatry, Columbia University / New York State Psychiatric Institute, New York, NY, (2)MindSpec Inc., McLean, VA*

Background:

A multifactorial model for ASD causation is increasingly recognized. Epidemiological family and twin studies have firmly established a genetic component underlying ASD with overall heritability estimates of approximately 50%. At the same time, these heritability estimates suggest the importance of non-genetic or environmental factors. Of the possible environmental risk factors for ASD, none has been studied as extensively as prenatal maternal infection, the subject of this review.

Objectives:

The objective of this study is to determine the association between maternal infection and fever and the risk of ASD through a meta-analysis of the extant literature.

Methods:

We conducted a comprehensive search of the PubMed and Google Scholar databases for peer-reviewed case-control studies and cohort studies written in English that examined the association between maternal infection during pregnancy and/or fever and/or antibiotics and the risk of ASD. The reference lists of retrieved articles were hand-searched for additional relevant articles. A total of 35 papers were ultimately included in the meta-analysis. From each paper, we extracted information pertaining to study design, the population under study, total number of subjects in each group, information regarding the type and timing of infection exposure, diagnostic criteria, outcome measures, and statistical adjustments. ORs were combined across studies using Comprehensive Meta-Analysis software (Borenstein et al. 2009). When individual articles examined multiple types of exposure, we collapsed both the effects to obtain study-level effects sizes (any infection or fever), and examined the exposure types separately in order to determine if there is heterogeneity of effect across infectious agents or across infections sites.

Results:

Study-level analyses revealed a modest, but significant effect of exposure to infection/fever on autism risk [OR=1.20;95%CI,1.07-1.35]. There is little or no heterogeneity by either infectious agent or infection site. Some heterogeneity exists across trimester of exposure, with first trimester exposures have slightly weaker effects than those occurring later, but these differences are not statistically significant. In rare instances when investigators considered variation in exposure severity (e.g. length of maternal exposure to fever) severity was often strongly related to effect size.

Conclusions:

Maternal exposure to infection confers a modest, but statistically reliable, average increase in risk of autism in offspring. The modest size of the increase risk suggests that the impact of maternal infection may need to be understood in terms of its interaction with other risk factors (e.g. genetic vulnerability). Although severity of exposure is under-studied, the larger odds ratios associated with lengthy bouts of fever, for example, suggests that these more severe exposures require fewer additional vulnerabilities to result in ASD. The absence of heterogeneity across infectious agent and site is consistent with the idea of a common mediator (e.g. markers of inflammation). The absence of heterogeneity across trimester could be the result of measurement error, or due to the relevant neurodevelopmental processes straddling these divisions.

123 **184.123** Interaction between Manganese and GSTP1 in Relation to Autism Spectrum Disorder While Controlling for Exposure to Mixture of Lead, Mercury, Arsenic, and Cadmium

M. H. Rahbar[1], *M. E. Samms-Vaughan*[2], *M. Lee*[1], *M. A. Bach*[3], *J. Bressler*[4], *M. Hessabi*[3], *M. L. Grove*[5], *S. Pellington*[2], *C. Coore Desai*[6], *J. A. T. Reece*[6], *K. A. Loveland*[7] *and E. Boerwinkle*[8], *(1)Division of Clinical and Translational Sciences, Department of Internal Medicine, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (2)Department of Child & Adolescent Health, The University of the West Indies, Mona Campus, Kingston, Jamaica, (3)Biostatistics/Epidemiology/Research Design (BERD) core, Center for Clinical and Translational Sciences (CCTS), The University of Texas Health Science Center at Houston, Houston, TX, (4)Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (5)Department of Epidemiology, Human Genetics, and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (6)Department of Child & Adolescent Health, The University of the West Indies, Kingston, Jamaica, (7)Department of Psychiatry and Behavioral Sciences, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (8)Department of Epidemiology, Human Genetics, and Environmental Sciences, Human Genetics Center, University of Texas School of Public Health at Houston, Houston, TX*

Background: Humans are regularly exposed to a combination of environmental chemicals, including heavy metals and metalloids, which have potentially neurotoxic effects. Although neurotoxic effects are known for some individual metals, there is limited published information on the combined neurotoxicity of heavy metals. It is possible that even when individual metals are below their ecotoxicological benchmark levels, interactions among a mixture of metals could result in more severe health effects. Several metals are known to induce oxidative stress, which has previously been linked with autism spectrum disorder (ASD). Glutathione S-transferase (GST) enzymes, encoded by genes in the *GST* gene family, play a protective role against oxidative stress. We have previously reported a significant interaction between polymorphisms of *GSTP1* and blood manganese concentrations (BMC) in relation to ASD in Jamaican children. However, we did not control for the potential confounding effect of the mixture of other metals.

Objectives: To investigate whether the interaction between *GSTP1* and blood manganese concentrations in relation to ASD will remain statistically significant after controlling for exposure to a mixture of four other metals, including lead, mercury, cadmium, and arsenic.

Methods: We used data from 163 pairs of Jamaican children 2-8 years of age enrolled in the Epidemiological Research on Autism in Jamaica (ERAJ) or ERAJ- Phase II matched case-control studies. To minimize any potential multicollinearity between blood concentrations of lead, mercury, arsenic, and cadmium, we used generalized weighted quantile sum (WQS) regression. Then, we used conditional logistic regression models to assess the interaction effect between *GSTP1* and manganese in relation to ASD, controlling for the weighted score of the four metals (i.e., WQS) and other potential confounders. In this analysis, we considered the co-dominant genetic model previously used to assess the interaction of *GSTP1* genotype and BMC in relation to ASD.

Results: We found that the interaction between *GSTP1* and blood manganese concentration remained significant after adjusting for the mixture of lead, mercury, cadmium, and arsenic and additional potential confounders. Using the co-dominant model for *GSTP1*, results indicated that among children with the Ile/Ile genotype, those with BMC ≥ 12µg/L had 4.6 times higher odds of ASD compared to those with BMC < 12µg/L (adjusted Matched Odds Ratio (MOR) = 4.6, 95% CI: 1.21 – 17.42).

Conclusions: Our previously published finding that *GSTP1* genotype may be an effect modifier for the association between binary blood manganese concentrations and ASD in Jamaica remained statistically significant after adjusting for the mixture effect of lead, mercury, cadmium, and arsenic. It is important to consider mixtures of environmental exposures when investigating their associations with ASD since exposures do not occur in isolation.

124 **184.124** Maternal Anxiety and Depression Are Associated with Autism Spectrum Disorder Phenotypes in Preschol Children

L. Wiggins[1], *E. Rubenstein*[2], *J. Daniels*[3], *C. DiGuiseppi*[4], *M. Yeargin-Allsopp*[1], *L. Schieve*[1], *L. Tian*[1], *K. R. Sabourin*[5], *E. Moody*[6], *J. A. Pinto-Martin*[7], *N. Reyes*[8] *and S. E. Levy*[9], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)Waisman Center at UW Madison, Madison, WI, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (5)University of Colorado Anschutz Medical Campus, Aurora, CO, (6)University of Colorado, Denver, Aurora, CO, (7)University of Pennsylvania, Philadelphia, PA, (8)JFK Partners, University of Colorado Anschutz Medical Campus, Aurora, CO, (9)Division of Developmental and Behavioral Pediatrics, Center for Autism Research, Children's Hospital of Philadelphia; Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA*

Background:

Anxiety and depression are common among individuals with autism spectrum disorder (ASD), and a number of studies have found maternal anxiety and depression to be associated with the development of ASD in offspring. Several studies highlighted an association between maternal depression and specific ASD phenotypes characterized by higher adaptive and cognitive functioning and increased rates of problem behaviors in the child with ASD.

Objectives:

We explored whether a history of maternal anxiety and depression was associated with ASD phenotypes in the child. We hypothesized that maternal anxiety or depression would be associated with a profile in children with ASD characterized by increased rates of anxiety and depression, average learning abilities, and mild language and motor delays.

Methods:

The Study to Explore Early Development (SEED) is a multisite, community-based study of children 30-68 months of age. SEED was designed to describe ASD phenotypes and investigate how genetic and environmental factors are associated with ASD profiles. Participants were 672 children with ASD and their mothers. Children with ASD were classified after a comprehensive developmental evaluation with gold-standard diagnostic instruments. Child ASD phenotypes were derived from latent class analysis of extensive behavioral, developmental, and medical data. Four phenotypes best described children with ASD: (1) *Mild Language Delay with Cognitive Rigidity,* (2) *Significant Developmental Delay with Repetitive Motor Behaviors,* (3) *General Developmental Delay,* and (4) *Mild Language and Motor Delay with Dysregulation (e.g., anxiety/depression) or "Dysregulated ASD*." Mothers completed a medical history questionnaire and reported whether a doctor diagnosed them with anxiety or depression before the birth of their child. To assess associations between maternal anxiety or depression and child phenotypic class, we conducted a multinomial logistic regression weighted for classification error and adjusted for confounding. Type 2 ASD (i.e., *Significant Developmental Delay with Repetitive Motor Behaviors)* was chosen as the reference category for regression analyses.

Results:

22.6% of mothers reported being diagnosed with anxiety or depression before the birth of their child. Type 4 or *Dysregulated ASD* was associated with a reported history of maternal anxiety or depression (Odds ratio 2.73, 95% confidence interval: 1.23, 5.46); and the association was stronger when both conditions were present (Odds ratio 4.73, (95% confidence interval: 1.35, 16.5). Maternal anxiety or depression was not associated with other ASD phenotypes.

Conclusions:

We conclude that maternal anxiety and depression are significantly associated with an ASD phenotype characterized by increased rates of anxiety and depression, typical learning abilities, and mild delays in language and motor skills in preschool children. Our findings highlight the potential for shared etiologic pathways between anxiety, depression, and *Dysregulated ASD* that can be explored in future research studies.

125 **184.125** The Influence of Diagnostic Criteria on Autism Spectrum Disorder Classification: Findings from the Metropolitan Atlanta Developmental Disabilities Surveillance Program, 2012

L. Wiggins*, D. Christensen and J. Baio, Centers for Disease Control and Prevention, Atlanta, GA*

Background:

The Centers for Disease Control and Prevention (CDC) has consistently applied a rigorous and reliable surveillance method to estimate the prevalence of autism spectrum disorder (ASD). This method employs a record-based coding scheme based on criteria outlined in the Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition – Text Revision (DSM-IV-TR). The American Psychiatric Association made considerable changes to ASD diagnostic criteria in 2013 (i.e., DSM-5) that influence CDC ASD surveillance methods.

Objectives:

The objectives of this study were to: (1) evaluate agreement between the DSM-IV-TR and DSM-5 surveillance definitions for ASD, (2) quantify the percentage of children who met only the DSM-IV-TR surveillance definition and the percentage of children who met only the DSM-5 surveillance definition, and (3) evaluate differences in characteristics of these latter two groups of children.

Methods:

A child was eligible for ASD surveillance if he/she: 1) was eight years old during the 2012 surveillance year, 2) had a legal guardian who resided in metropolitan Atlanta, GA, and 3) was served for a developmental condition as evidenced by a discharge diagnosis, billing code, reason for referral, or education eligibility noted in evaluation records. Surveillance staff reviewed health and education records of eligible children for social deficits characteristic of ASD (e.g., limited interest in other children). All records that contained a social deficit were abstracted to collect accounts of developmental history, ASD symptoms, developmental tests, and co-occurring conditions diagnosed by the community professional who evaluated the child. Clinicians with advanced degrees and specialized training and experience in ASD then applied two standardized coding schemes to the abstracted data: one based on DSM-IV-TR criteria that has previously been used to estimate ASD prevalence, and another based on DSM-5 criteria that was developed for this project and future surveillance efforts.

Results:

Results found substantial agreement between the DSM-IV-TR and DSM-5 surveillance classifications of ASD (kappa=0.80). There were no differences in child race/ethnicity, child sex, or intellectual disability between children who met only the DSM-IV-TR surveillance definition and those who met only the DSM-5 surveillance definition. Children who met the DSM-IV-TR but not the DSM-5 surveillance definition (4% of the sample) were more likely to have developmental concerns and evaluations in the first three years. Children who met the DSM-5 but not the DSM-IV-TR surveillance definition (6% of the sample) were more likely to have been receiving autism-related services or previously diagnosed with ASD.

Conclusions:

The ASD surveillance definition based on DSM-5 criteria is largely comparable to that based on DSM-IV-TR criteria, and both identify children with similar demographic and intellectual characteristics. DSM-IV-TR surveillance criteria may detect few children with long-standing social-communication concerns that do not meet the number and pattern of deficits specified in DSM-5. DSM-5 surveillance criteria may detect few children who have an ASD diagnosis and are not captured with DSM-IV-TR surveillance. CDC record-review surveillance is uniquely equipped to continue to evaluate the influence of diagnostic criteria on ASD classification and prevalence estimates in large and diverse samples of children.

126 **184.126** Maternal Cannabis Use in Pregnancy and Autism Spectrum Disorder in the Charge Study

P. Krakowiak[1]*, R. J. Schmidt*[2]*, D. Tancredi*[3]*, R. L. Hansen*[4]*, S. Ozonoff*[5]*, I. Hertz-Picciotto*[6] *and C. K. Walker*[7]*, (1)UC Davis, Sacramento, CA, (2)Public Health Sciences, University of California Davis, Davis, CA, (3)UC Davis School of Medicine, Sacramento, CA, (4)University of California Davis, Davis, CA, (5)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (6)University of California at Davis, Davis, CA, (7)University of California, Sacramento, CA*

Background: Cannabis use has been associated with deficits in verbal and memory domains, as well as inattention, impulsivity and hyperactivity in young children evaluated in historical cohorts likely to underestimate the impact of current fetal cannabis exposure.
Objectives: To determine whether maternal cannabis use in pregnancy is associated with adverse neurodevelopment in a case-control study designed to evaluate the effects of environmental and genetic factors on autism spectrum disorder (ASD) and developmental delay (DD).

Methods: The Childhood Autism Risks from Genetics and the Environment (CHARGE) study is a population-based, case-control investigation of ASD and/or DD origins. Children from 20 California counties aged 24 to 60 months and living in catchment areas with a biological parent fluent in English or Spanish were enrolled from 1/29/2003 to 1/23/2017. Children with ASD (n = 725) and DD (n = 288) were recruited through the California Department of Developmental Services, the Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, and referrals. Controls with typical development (TD) (n = 494) were randomly selected from birth records and frequency matched on age, sex, and broad geographic region. Maternal self-report of prenatal cannabis use and other exposures were drawn from a telephone interview conducted in English or Spanish. The Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview–Revised (ADI-R) were used to confirm ASD, whereas children with DD and TD were confirmed by Mullen Scales of Early Learning (MSEL) and Vineland Adaptive Behavior Scales (VABS) and were free of autistic symptoms. Multinomial logistic regression models that controlled for maternal factors were developed to examine the association between cannabis and developmental outcomes.

Results: Of women who reported cannabis use, nearly all (93%) used marijuana, with only 7% using cannabinoids. Reported use in CHARGE controls reflected published prevalence: 6.1% during the 3 months prior to conception and 2.0% at any time during pregnancy, with frequencies declining across the three trimesters (1.8%, 0.9%, 0.7%). Cannabis use was most prevalent among mothers of children with ASD (4.6%) followed by mothers of children with DD (2.6%) and controls (2.0%). After adjusting for maternal race/ethnicity, education, and tobacco use during pregnancy, cannabis use was not significantly associated with ASD risk (1.76; 95%CI, 0.78, 3.97). Further preliminary analyses revealed that tobacco use operated in models both as a confounder and effect modifier (p=0.01). There was evidence of a multiplicative effect between tobacco and cannabis use on the likelihood of ASD; exposure to both substances during pregnancy compared to neither significantly increased the risk of ASD whereas exposure to either one alone did not. However, the stratified data are sparse and results are preliminary. Cannabis use was not associated with DD.

Conclusions: Widespread legislation decriminalizing cannabis use and enhancing availability has led to dramatic increases in use and a growing perception that cannabis exposure – both overall and in pregnancy – is safe. Our findings suggest that fetal exposure to cannabis alone does not increase ASD risk. However, the combined use of cannabis and tobacco may be hazardous to fetal neurodevelopment.

127 **184.127** Maternal Metabolic Conditions and ASD: Comparing Associations from High-Risk and General Populations

P. Krakowiak[1], *D. Tancredi*[2], *R. L. Hansen*[3], *I. Hertz-Picciotto*[4] *and C. K. Walker*[5], *(1)UC Davis, Sacramento, CA, (2)UC Davis School of Medicine, Sacramento, CA, (3)University of California Davis, Davis, CA, (4)University of California at Davis, Davis, CA, (5)University of California, Sacramento, CA*

Background: The association between maternal metabolic dysfunction – in the form of obesity, hypertensive disorders, diabetes or specific physiologic biomarkers – and autism spectrum disorder (ASD) is one of the most consistent findings in ASD epidemiology.
Objectives: To compare associations between maternal metabolic conditions and ASD in children in the MARBLES (cohort of high-risk mothers and CHARGE population-based case-control studies in California.

Methods: Participants included 156 mother-child pairs (45 with ASD) from the MARBLES prospective cohort of pregnant women who have a biological child with ASD and followed until the child reaches 36 months; and 676 ASD cases and 467 controls from the CHARGE population-based case-control study. Metabolic conditions in both studies were ascertained using medical records and structured telephone interviews with the mother, and conditions included diabetes (type 2 or gestational), hypertension (chronic or gestational, preeclampsia), and prepregnancy obesity (body mass index ≥30). In both studies, ASD diagnosis was assessed with Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview–Revised (ADI-R); typical development was determined using the Mullen Scales of Early Learning (MSEL) and Vineland Adaptive Behavior Scales (VABS), with composite scores ≥70 on both assessments.

Results: Preliminary findings showed a higher prevalence of metabolic conditions in MARBLES compared with CHARGE among mothers whose child was diagnosed with ASD. Overall, 47% of MARBLES mothers were burdened with metabolic conditions (diabetes, hypertensive disorder, and/or obesity) in contrast to 35% of CHARGE mothers. Twenty-two percent of MARBLES mothers, compared to 9.8% of CHARGE mothers, had diabetes (mainly the gestational form). Metabolic conditions were also more prevalent in MARBLES mothers of typically developing children in contrast to CHARGE, with 38% compared to 25% affected. Time trends, population composition, and the choices in comparison groups will be evaluated and discussed.

Conclusions: These comparisons are unique in that the two analyses employ the same extensive exposure and outcome ascertainment techniques. This allows an analysis focused on the influence of study design, population and time frame on the association between maternal metabolic conditions and ASD. The CHARGE case-control design enrolled children with specific diagnoses who may or may not have had siblings, while the MARBLES enriched cohort design recruited families with a ASD-affected child and assessed neurodevelopmental outcomes in subsequent offspring. Compared with CHARGE, MARBLES pregnancies occurred later temporally; mothers were likely to be older; and children diagnosed with ASD became part of multiplex families, which are more likely to have shared genetic risk factors. Analyses restricted to overlapping birth years and adjusted for maternal education, and race/ethnicity are planned, as is a comparison of multiplex and simplex CHARGE families.

128 **184.128** Maternal Exposures Associated with Autism Spectrum Disorder in Jamaica

M. A. Bach[1], *M. E. Samms-Vaughan*[2], *M. Lee*[3], *J. Bressler*[4], *M. Hessabi*[1], *M. L. Grove*[5], *S. Pellington*[2], *C. Coore Desai*[6], *J. A. T. Reece*[6], *K. A. Loveland*[7], *E. Boerwinkle*[8] *and M. H. Rahbar*[3], *(1)Biostatistics/Epidemiology/Research Design (BERD) core, Center for Clinical and Translational Sciences (CCTS), The University of Texas Health Science Center at Houston, Houston, TX, (2)Department of Child & Adolescent Health, The University of the West Indies, Mona Campus, Kingston, Jamaica, (3)Division of Clinical and Translational Sciences, Department of Internal Medicine, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (4)Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (5)Department of Epidemiology, Human Genetics, and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (6)Department of Child & Adolescent Health, The University of the West Indies, Kingston, Jamaica, (7)Department of Psychiatry and Behavioral Sciences, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (8)Department of Epidemiology, Human Genetics, and Environmental Sciences, Human Genetics Center, University of Texas School of Public Health at Houston, Houston, TX*

Background: Autism Spectrum Disorder (ASD) is a complex neurodevelopmental disorder with poorly defined etiology. Many genetic and environmental factors may be involved in the manifestation of ASD, and most cases are thought to result from gene-environment interactions. Since neurodevelopment begins during the first few weeks of pregnancy and continues after birth, exposures experienced by the mother during pregnancy or breastfeeding have the potential to interrupt fetal and infant neurodevelopmental mechanisms and possibly contribute to disorders such as ASD. Maternal exposures that are believed to have adverse effects on neurodevelopment include bacterial and viral infections, physical trauma, and pesticides and other products containing volatile organic compounds.

Objectives: To investigate the associations of ASD in Jamaican children with maternal exposures, including fever over 101ºF or infection requiring antibiotics, physical trauma such as a car accident or fall, degreasers, oil-based paints, paint solvents, and pesticides or herbicides.

Methods: We used data from 298 pairs of Jamaican children 2-8 years of age enrolled in the Epidemiological Research on Autism in Jamaica (ERAJ) or ERAJ- Phase II matched case-control studies to assess the associations of maternal exposures with ASD in Jamaican children. Conditional logistic regression models were used for all crude and adjusted analyses. Potential confounders were included in the model if the magnitude of the adjusted matched odds ratio (MOR) differed from the crude MOR by ≥10% or if they are considered important potential confounders according to published literature. We also used conditional logistic regression models to investigate interactions between maternal exposures in relation to ASD in Jamaican children.

Results: After adjusting for potential confounders, maternal exposures to fever or infection (adjusted MOR = 3.12, 95% CI: 1.74 – 5.60), physical trauma (adjusted MOR = 2.02, 95% CI: 1.01 – 4.05), and oil-based paints (adjusted MOR = 1.99, 95% CI: 1.14 – 3.46) were significantly associated with ASD in the children. Further investigation revealed that maternal exposure to oil-based paints may be an effect modifier for the relationship between maternal exposure to pesticides or herbicides and ASD. Specifically, the association between maternal exposure to pesticides or herbicides and ASD in Jamaican children was stronger among those with maternal exposure to oil-based paints (MOR = 2.45, 95% CI: 1.41 – 4.26) compared to those without maternal exposure to oil-based paints (MOR = 1.74, 95% CI: 1.29 – 2.35).

Conclusions: Our findings suggest that maternal exposures to fever or infection, physical trauma, and oil-based paints occurring from 3 months before conception until the end of breastfeeding may be associated with ASD in Jamaican children. Additionally, maternal exposure to oil-based paints may modify the association between maternal exposure to pesticides or herbicides and ASD in Jamaican children. These findings require replication in other populations.

129 **184.129** Maternal Infection and Fever during Pregnancy and Risk of Autism Spectrum Disorder: Findings from the Study to Explore EARLY Development (SEED)

L. A. Croen[1], *Y. Qian*[1], *P. Ashwood*[2], *O. Zerbo*[3], *D. Schendel*[4], *J. A. Pinto-Martin*[5], *M. D. Fallin*[6], *S. E. Levy*[7], *L. Schieve*[8], *M. Yeargin-Allsopp*[8] *and K. R. Sabourin*[9], *(1)Division of Research, Kaiser Permanente, Oakland, CA, (2)MIND Institute, University of California, Davis, Davis, CA, (3)Kaiser Permanente, Oakland, CA, (4)Public Health, Aarhus University, Aarhus, Denmark, (5)University of Pennsylvania, Philadelphia, PA, (6)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (7)Division of Developmental and Behavioral Pediatrics, Center for Autism Research, Children's Hospital of Philadelphia; Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, (8)Centers for Disease Control and Prevention, Atlanta, GA, (9)University of Colorado Anschutz Medical Campus, Aurora, CO*

Background: Evidence from animal and human studies indicates that in utero exposure to maternal immune activation can adversely impact neurodevelopment. Maternal infection and fever during pregnancy have been implicated in the etiology of autism spectrum disorder (ASD) in several studies; however, studies have not been able to separate the effects of fever itself from the impact of a specific infectious organism on the developing brain.

Objectives: To investigate specific types of infection during pregnancy, the timing of exposure, and the impact of fever associated with those infections, and their association with ASD and other developmental disorders (DD) in the child.

Methods: The study population was drawn from the Study to Explore Early Development, a multi-site case-control study conducted in six sites across the United States among children born between 2003-2006. Three groups of children were enrolled at 2-5 years of age. For each enrolled child, final study group classification (ASD, DD, general population control (POP)) was determined by an in-person standardized developmental assessment. Infection and fever during pregnancy were ascertained via maternal interview conducted over the telephone shortly after study enrollment and review of maternal medical records. For each infection reported, the mother was asked to specify the timing during pregnancy, the types of medications taken, and whether fever was present. Infection was classified according to microorganism type (e.g. bacterial, viral, etc.) and organ system affected. For each exposure definition, separate unadjusted and adjusted logistic regression models were run to estimate the association with ASD (vs. POP) and DD (vs. POP) by trimester of exposure. Covariates included in adjusted analyses were maternal race/ethnicity, education, age at delivery, psychiatric condition history, and hypertension, household income during pregnancy, child’s sex, and study site.

Results: The final analytic sample included 606 with ASD, 856 with DD, and 796 POP. Approximately 60% of mothers in each study group experienced an infection during pregnancy. Bacterial infection was the most common maternal infection type during pregnancy, occurring in roughly a third of the population, and significantly more often in mothers of children with ASD than mothers of POP controls (36.3% vs. 31.3%, P=0.05). After adjustment for covariates, maternal infection anytime during pregnancy was not associated with ASD or DD. No significant associations with ASD or DD were observed for infections with specific organ systems or specific microorganism types in any time period. However, second trimester infection accompanied by fever was associated with approximately 2-fold increase in odds of ASD (adjusted odds ratio=2.19, 95% confidence interval 1.14-4.23). Neither infection with fever nor infection without fever during pregnancy increased risk for DD.

Conclusions: Our findings suggest that maternal infection with fever in the second trimester is associated with ASD. These findings suggest that perhaps the immune response rather than the infectious agent is etiologically relevant. Future studies with increased sample size could help provide more detailed analyses on type and timing of maternal exposure to infection and fever and specific developmental outcomes in the child to elucidate potential biologic mechanisms underlying the associations reported here.

130 **184.130** Maternal Prenatal Vitamin Use and Risk for Autism Spectrum Disorder in the Marbles Prospective Study of Enriched-Risk Siblings

R. J. Schmidt[1,2], *A. M. Iosif*[1], *E. Angel*[1] *and S. Ozonoff*[3], *(1)Public Health Sciences, University of California Davis, Davis, CA, (2)MIND Institute, University of California, Davis, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA*

Background:

In population-based studies, maternal periconceptional folic acid intake has been inconsistently associated with reduced risk for autism spectrum disorder (ASD) in the child. No study to date has examined the association with recurrence risk in a prospective study of enriched-risk families having children with ASD.

Objectives:

To examine whether maternal prenatal vitamin supplementation was associated with decreased ASD risk in subsequent siblings of children with ASD.

Methods:

Design: MARBLES (Markers of Autism Risk in Babies: Learning Early Signs) prospective pregnancy cohort study of younger siblings of children with ASD who were born from 2006-2013 and followed up to 3 years of age.

Setting: Participants within driving distance to the University of California Davis MIND Institute in Sacramento, California recruited primarily from the families receiving services for children with ASD in the Department of Developmental Services.

Participants: 205 younger siblings at high risk for ASD born to 189 mothers in the MARBLES cohort study by December 31, 2013 and received algorithmic clinical diagnoses at 3-years.

Exposure: Prenatal vitamin use prospectively collected through maternal interviews, including information which months they were taken from 6 months before pregnancy, throughout pregnancy, and while breastfeeding, how often they were taken, and at what dose.

Primary Outcome: Algorithmic diagnosis of ASD, other non-typical development (Non-TD), or typical development was determined based on scores on the Autism Diagnostic Observation Schedule and the Mullen Scales of Early Learning.

Results:

Children whose mothers reported taking a prenatal vitamin during the first month of pregnancy were less likely to be diagnosed with ASD than children whose mothers did not report taking a prenatal vitamin in pregnancy month one ($RR_{adjusted}$ = 0.47 [95% CI, 0.25 to 0.78]).

Conclusions:

Taking prenatal vitamin supplements daily during the first month of pregnancy could reduce ASD in subsequent high-risk children. Additional research is needed to confirm these results and investigate mechanisms to inform public health recommendations for ASD prevention in affected families.

131

184.131 Maternal Thyroid Anomalies and Risk of ASD

R. S. Rotem[1], *G. Chodick*[2], *M. Davidovitch*[3], *R. Hauser*[1], *B. A. Coull*[1], *G. Koren*[2] *and M. Weisskopf*[1], *(1)Harvard T.H. Chan School of Public Health, Boston, MA, (2)Maccabi Institute for Research and Innovation, Tel Aviv, Israel, (3)Medical Division, Maccabi Healthcare Services, Tel Aviv, Israel*

Background:

Thyroid hormones are essential for appropriate fetal brain development. The hormones play pivotal roles in numerous key neurodevelopmental processes, including fetal neural cells migration and synapse formation. Some preliminary evidence suggests that hypothyroidism or hypothyroxinemia is associated with autism spectrum disorders (ASD), but available data are inconsistent and rely heavily on cross-sectional observations. Moreover, the fetus is dependent on maternal supply of thyroid hormones during the first months of gestation. Very low levels of maternal thyroid hormones have been associated with reduced IQ and cretinism in the child, but the effects of more minor maternal thyroid conditions are less clear.

Objectives:

To evaluate the risk of ASD in children born to mothers with thyroid anomalies, and the relation between maternal thyroid hormone levels during pregnancy and risk of ASD.

Methods:

The study included 436,188 singleton pregnancies ending in a live birth occurring between January 1, 1999 through December 31, 2013 in a large sick fund in Israel. Data on ASD diagnoses, maternal thyroid conditions, drug dispensing information and lab results were obtained through December 31,2016. Mothers with thyroid conditions were identified through ICD-9 codes with subsequent validation of the diagnoses through review of medication dispensing data and laboratory results. ASD cases were identified through ICD-9 codes with further verification of case status through review of medical records. Analyses of thyroid abnormality diagnoses were performed using generalized estimating equation (GEE) logistic regression models with adjustment for potential confounders. Analysis of gestational lab test results was performed using general additive models using penalized splines.

Results:

Mothers who had ever experienced hypothyroidism were at a higher risk of giving birth to a child with ASD compared to women without thyroid conditions (OR=1.24, 95% C.I:1.08-1.41). Further stratification based on the time of first diagnosis relative to the birthdate of the child suggested that the effect was mostly driven by diagnoses given prior to birth (OR=1.27, 1.08-1.50), although borderline statistically significant effects were also seen with diagnoses first given post-birth (1.18, 0.98-1.42). Analysis of pregnancy TSH levels and ASD risk suggested an inverted U-shaped dose-response curve, with higher risks at moderately-elevated levels but not at the highest levels. Associations between hyperthyroidism and ASD were less consistent.

Conclusions:

The results suggest that maternal hypothyroidism could be a risk factor for ASD. The attenuated effects at the highest pregnancy TSH levels could be due to the higher prevalence of women subsequently treated with thyroid replacements, or indicate other differences in this subgroup. This attenuation may suggest that starting treatment for mothers with borderline low thyroid dysfunction could be beneficial and potentially indicate that thyroid screening in pregnant women, especially those with a history of thyroid anomalies, should be considered. Since thyroid levels are highly influenced by numerous environmental triggers, the possible role of maternal thyroid anomalies in ASD needs further exploration.

132

184.132 Maternal Vitamin D Levels during Pregnancy and Autism Spectrum Disorders (ASD)

G. C. Windham[1], *M. Pearl*[1], *V. Poon*[2], *J. Carver*[2], *D. Eyles*[3], *K. Lyall*[4], *K. L. Jones*[5], *M. Kharrazi*[6] *and L. A. Croen*[7], *(1)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (2)Sequoia Foundation, La Jolla, CA, (3)Queensland Brain Institute, University of Queensland, St Lucia, Australia, (4)A.J. Drexel Autism Institute, Philadelphia, PA, (5)University of California at Davis MIND Institute, Davis, CA, (6)CA Department of Public Health, Richmond, CA, (7)Division of Research, Kaiser Permanente, Oakland, CA*

Background: Vitamin D deficiency has increased concurrently with the rise in prevalence of Autism Spectrum Disorder (ASD), and evidence for vitamin D's role in brain and immune function has led to interest in potential associations with ASD. Prior studies of ASD have examined surrogates of vitamin D or levels after diagnosis, not during critical fetal developmental periods. Published studies with Vitamin D measured during pregnancy have not been specific to ASD, but rather for broader aspects of neurodevelopment. We previously reported no association of newborn Vitamin D levels and ASD and here examine another susceptibility period.
Objectives: To examine maternal Vitamin D levels in mid-pregnancy in association with ASD in offspring, and to explore potential differences by phenotype (ASD with and without comorbid intellectual disability (ID)) or demographic sub-groups.

Methods: Data are drawn from a case-control study among children born 2000-2003 in Southern California who had banked biospecimens available from routine genetic screening. Autism cases were identified through the CA Department of Developmental Services and controls were selected from general population births in the same area and birth years. 25-Hydroxyvitamin D (OHD) was measured in serum (N=534 cases, 421 controls) collected at 14-20 weeks gestation using a sensitive assay (as OHD2 and OHD3, then summed). OHD levels were categorized as deficient (<50nmol/L), insufficient (50-74nmol/L) and sufficient (≥75nmol/L, referent category), and also examined continuously. Linearity was assessed through generalized additive models and addition of a quadratic term in logistic models. Crude and adjusted odds ratios (AOR) and 95% confidence intervals (95%CI) were calculated.

Results: OHD was deficient in 9.5% and insufficient in 25.6% of mothers, with AORs (95%CI) for ASD of 0.79 (0.49-1.3) and 0.94 (0.68-1.3) respectively. There was also no association of linear continuous OHD levels. Results were consistent for ASD with or without ID. However, when stratified by maternal race/ethnicity, non-Hispanic Whites had the expected protective association with higher OHD levels (AOR=0.92, 95%CI=0.85-0.99 per 10nmol/L OHD), but other race/ethnic groups did not. Upon further exploration, a non-linear pattern, inverted j-shape, was observed overall between OHD and ASD (adjusted beta for quadratic term = -0.0001, p=0.02), with the peak around 100 nmol/L. This pattern was similar when examining OHD3 separately or for ASD by comorbid ID. By maternal race/ethnicity, this pattern was attenuated in the non-Hispanic Whites and more apparent in "other" race/ethnic groups.

Conclusions: In one of the first large studies to examine prenatal Vitamin D levels in relation to clinical ASD, we saw no association overall with Vitamin D deficiency/insufficiency or continuous levels, in contrast to hypotheses. However a significant non-linear association was observed and high levels of Vitamin D appear to be protective, particularly among White mothers. Race differences may in part be due to variation in OHD levels, with White women having a distribution shifted to higher levels. The suggestive finding of protective effects as well at lower Vitamin D levels requires further investigation to explain. Future analyses will also examine co-exposures to organo-halogenated compounds and genetic interactions.

133 **184.133** Mental Comorbidities, Psychotropic Medication Use and Healthcare Resource Use in Autism Spectrum Disorder: A Matched Cohort Study in the United Kingdom.

R. Houghton[1], *C. Liu*[2] *and F. Bolognani*[3], *(1)Real World Data Science, F.Hoffman La-Roche Ltd, Basel, Switzerland, (2)Real World Data Science, Roche (China) Holding Ltd, Shanghai, China, (3)Neuroscience, Ophthalmology, and Rare Diseases (NORD), Roche Pharma Research and Early Development, Roche Innovation Center Basel, F. Hoffmann - La Roche AG, Basel, Switzerland*

Background: Psychiatric comorbidities and use of psychotropic medications are common among patients with autism spectrum disorder (ASD). Most previous work in this area used data from the United States, and few studies have compared medication use in ASD to control groups.
Objectives: The objective of this study was to investigate psychiatric comorbidities, psychotropic medication use and resource utilization in patients with ASD in the United Kingdom (UK), as well as to compare these outcomes to the general population and to patients with attention deficit hyperactivity disorder (ADHD). We also estimated associations between patient characteristics and the probability of being prescribed psychotropic medications in ASD.

Methods: We conducted a cohort study using primary care data from the Clinical Practice Research Datalink (CPRD) database. The main study period was the calendar year 2015. We identified a prevalent cohort of patients with ASD and two comparison cohorts -- namely, a general population and an ADHD cohort, both matched by age, sex and region. We described mental comorbidities, use of psychotropic medications, and healthcare utilization (GP visits and referrals to secondary care) in all three cohorts. For the ASD cohort we used regression models to investigate patient characteristics associated with psychotropic medication use, polypharmacy (2 classes of psychotropic medications at the same time) and the number of visits to the GP. Lastly, we compared medication and resource use in ASD to the control cohorts using conditional logistic regression models.

Results: A total of 10,856 ASD patients were included in the study. The majority were male (81%) and the mean (SD) age was 18.76 (11.86) years. Psychiatric comorbidities were recorded in 41.5% of all ASD patients, with sleep disturbances (14.9%) and ADHD (13.8%) being the most common. Thirty-two percent of ASD patients received a psychotropic medication prescription, with anxiolytics/sedatives/hypnotics (14.2%), antidepressants (12.8%) and antipsychotics/tranquilizers (8.3%) being the most common. Eighty-six percent of ASD patients had visits to primary care, while 18.9% were referred to secondary care. Increased age and female gender increased the likelihood of both psychotropic medication use and healthcare resource utilization, as did the majority of the psychiatric comorbidities studied.

ASD patients were more likely to take psychotropic medications and visit primary care more frequently than the general population. However they were less likely to have these outcomes compared to ADHD patients. For drug use, this was largely driven by the prescription of stimulants.

Limitations: The study is limited to data entered in primary care.

Conclusions: People with ASD were more likely to receive medication and use healthcare resources than the general population, but less likely, compared to people with ADHD. Psychiatric comorbidities and psychotropic medication use are common in ASD in the UK. In a 1-year period, 1/3 of ASD patients received a primary care prescription for a psychotropic medication.

134 **184.134** Migration and Risk of Autism and Intellectual Disability – Preliminary Findings from the Stockholm Youth Cohort

C. Magnusson[1]*, H. Heuvelman*[2]*, M. Morinaga*[1]*, A. C. Hollander*[1]*, C. Dalman*[3] *and D. Rai*[4]*, (1)Karolinska Institutet, Stockholm, Sweden, (2)University of Bristol, Bristol, United Kingdom of Great Britain and Northern Ireland, (3)Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden, (4)Population Health Sciences, Bristol Medical School, Centre for Academic Mental Health, Bristol, United Kingdom*

Background: Parental migration status is an emerging risk factor for autism spectrum disorder (ASD) and perhaps also for intellectual disability (ID). The foundation of any association is, however, not established.
Objectives: To elucidate whether migration status is universally linked to neurodevelopmental disorders or specifically to ASD or ID, and how any link varies with parental region of origin. In addition, to investigate how any relationships may be explained by migration-related by comparing risks between full siblings discordant for maternal migrant status (siblings being born in Sweden versus abroad).

Methods: Total population study based on linkages of health and administrative registers, including 545,648 individuals born in 1984-2007, who were resident in Stockholm County, Sweden for at least four years through 2011. Migration status was defined according to parental country of birth and timing of maternal immigration to Sweden in relation to the index persons' birth. Odds ratios (ORs) from total cohort analyses were adjusted for age, sex, maternal and paternal age, using generalized estimating equation models to account for family clustering. Sibling comparisons were adjusted for sex.

Results: In all, 11,163 and 6,845 individuals were respectively identified with diagnoses of ASD and ID during follow-up. Children of migrant parents had an increased risk of autism with co-morbid ID (aOR 1.69, 95% CI 1.54 - 1.85) and of ID only (aOR 1.74, 95% CI 1.61 - 1.87), but a decreased risk of ASD without ID (aOR 0.56, 95% CI 0.52 - 0.60).These associations were particularly pronounced in children of parents from low-income countries. Timing of maternal migration in relation to birth of the index child appeared to influence the risk of ASD (but not ID only), such that the risk increased with increasing nearness of immigration to the timing of pregnancy. Individuals born in Sweden had a twofold increase in risk of ASD regardless of comorbid ID compared to their full siblings born abroad, while no such discrepancy for ID only was observed.

Conclusions: Parental origin in low-income countries is strongly associated with ID, with or without ASD in Stockholm County – but the explanatory mechanisms may differ between ASD with ID and ID only. ASD without ID is comparatively less often diagnosed in children of migrants to Sweden.

135 **184.135** Neonatal Markers of Infant Behavior and Quantitative Traits Related to Autism Spectrum Disorders in a Longitudinal Birth Cohort Study

S. Sagiv[1]*, K. Kogut*[1]*, Y. S. Kim*[2]*, J. Deardorff*[1] *and B. Eskenazi*[1]*, (1)Center for Environmental Research and Children's Health, UC Berkeley School of Public Health, Berkeley, CA, (2)University of California San Francisco, San Francisco, CA*

Background: Identification of antecedent markers of neurodevelopmental disorders like autism spectrum disorders (ASD) can help to target interventions at earlier ages. Prospective cohort studies that assess children in infancy are uniquely positioned to examine early markers in relation to quantitative traits related to ASD later in childhood.
Objectives: To investigate associations of infant behavior, including the capacity to regulate internal state and respond to environmental stimuli, on quantitative traits related to ASD, measured in adolescence.

Methods: The CHAMACOS (Center for Health Assessment of Mothers and Children of Salinas) longitudinal birth cohort study investigates the health of pregnant women and their children living in a predominantly Mexican-American agricultural community. We recruited pregnant women ≥18 years old and <20 weeks gestation between October 1999 and October 2000 at prenatal clinics serving the Salinas Valley. Of the 528 live births in CHAMACOS, we administered the Brazelton Neonatal Behavioral Assessment Scale (NBAS) to 419 infants (median (25th-75%ile) age: 9 (1-25) days). The NBAS measures 27 behavioral and 18 reflex items; we used the Lester scoring method (Lester et al. 1982) to distill these items into seven clusters: Habituation, Orientation, Motor, Range of State, Regulation of State, Autonomic Stability, and Reflex. When the CHAMACOS children were age 14 years, parents of 212 children with an NBAS were administered the Social Responsiveness Scale, Second Edition (SRS-2), a rating scale that quantifies the frequency of traits in their children related to social behavior and stereotypic behavior/restricted interests. We fit multivariable regression models to estimate associations of NBAS cluster scores with SRS-2 scores, adjusting for infant's age (days) at NBAS, child's sex, number of years the mother lived in the U.S., language the mother used to complete the SRS-2, maternal depression and a measure of the home environment (HOME score).

Results: Mean (standard deviation) SRS-2 Total T-score for 212 children with an NBAS was 55.5 (7.4), with 23 children scoring at or above the cut-off at which screening for ASD is recommended (raw score of 70). We found associations of poorer regulation in infancy (e.g., less self-quieting, poorer consolability) with higher odds of maternal-reported adolescent ASD traits in the range recommended for ASD screening (OR=1.60; 95% CI: 1.02, 2.51). In contrast, infants with poorer motor performance (e.g. less physical maturity, lower tone) had lower odds of meeting the threshold for ASD screening in adolescence (OR=0.43; 95% CI: 0.19, 0.99).

Conclusions: We found that regulation of state and motor function in infancy were associated with quantitative traits related to ASD in adolescence. Data from this longitudinal cohort contribute to a growing literature suggesting that early life markers may help to identify children that will later develop symptoms consistent with a diagnosis of ASD. This can have important implications for targeting intervention earlier with the goal of improving the lives of individuals living with ASD.

136 **184.136** Placental Trophoblast Inclusions Do Not Predict Adverse Neurodevelopment in the Marbles High-Risk Pregnancy Cohort

C. K. Walker[1]*, K. Kim*[2]*, S. Ozonoff*[3] *and I. Hertz-Picciotto*[4]*, (1)University of California, Sacramento, CA, (2)Division of Biostatistics, Department of Public Health Sciences, University of California, Davis, Cavis, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (4)University of California at Davis, Davis, CA*

Background: Presence of placental trophoblast inclusions (TIs) has been shown to predict autism spectrum disorder (ASD) *risk* status, but there are no data to support its potential as a biomarker for *actual* adverse neurodevelopment.
Objectives: The purpose of this study was to determine whether the presence and/or frequency of placental TIs is associated with adverse neurodevelopmental outcomes in a population at enhanced risk for ASD.

Methods: Placental samples were obtained from 117 births in the MARBLES (Markers of Autism Risk in Babies – Learning Early Signs Study) longitudinal ASD-risk birth cohort between January 11, 2008 and January 10, 2011. Four slides per specimen were examined histologically in random order for TIs, identified as a central syncytiotrophoblast nucleus surrounded by one or more cytotrophoblasts. TIs were summed across slides. Child development was evaluated at 36 months of age with Autism Diagnostic Observation Schedule (ADOS) and Mullen Scales of Early Learning (MSEL). Outcome was established by two methods: 1) clinical best estimate (CBE), categorized as ASD (n=21), other developmental concerns (ODC, n=20), or typical development (TD, n=63); and 2) an algorithm incorporating multiple clinical assessments, ADOS and MSEL scores that classified diagnoses as ASD (n=29), non-typical development (NTD, n=9) and TD (n=55). Children with final outcomes were included for statistical analysis. The pathology team was blinded to outcome and those assessing neurodevelopmental function were blinded to TI status.

Multinomial logistic regression models were performed to assess the association between TI frequency (continuous and dichotomous [0-1 negative and ≥2 positive]) and child outcome defined by CBE and algorithm, with and without adjustment for important covariates. We explored each covariate in a stepwise fashion and retained only those that altered the TI coefficient by at least 20%, considering the sample size. Final models included maternal age, education, race/ethnicity and diabetes; paternal age, and child sex as covariates.

Results: TI presence did not predict child developmental outcome in any of the permutations analyzed. For example, results comparing odds of ASD v TD by number of TIs were null and did not vary by outcome categorization (CBE: 0.84, 0.61-1.15 and Algorithm: 1.02, 0.84-1.24]). Both univariate and covariate-adjusted statistical analyses failed to identify any significant association between TIs and either ASD or more subtle neurodevelopmental impairments.

Conclusions: Because TIs have been associated with being *at risk* for ASD in the same way that having an older affected sibling is a marker for increased susceptibility, TIs may identify a predisposition, genetic or otherwise, for ASD. However, placental TIs demonstrated no association with the development of ASD or of other non-typical neurodevelopmental outcomes. The evidence to date provides no justification for use of placental TI presence as a predictive biomarker for ASD in either at-risk or low-risk populations.

137 **184.137** Predictors and Impact of Non-Response in a Population-Based Case Control Study: Findings from the Georgia Study to Explore Early Development

*L. Schieve, S. Harris, M. J. Maenner, **A. Alexander** and N. Dowling, Centers for Disease Control and Prevention, Atlanta, GA*

Background: Participation in epidemiologic studies has declined over time, raising concerns about selection bias. While estimates derived from epidemiologic studies have been shown to be robust under a wide range of scenarios, additional empiric study is needed. Empiric assessments of non-response are inherently challenging given the lack of information available on non-responders in most studies, including those of autism spectrum disorder (ASD). We explore factors associated with non-participation and its potential impact on associations between ASD and various risk factors in the Georgia Study to Explore Early Development (GA SEED).
Objectives: N/A

Methods: GA SEED is a population-based case-control study of risk factors for ASD that recruited children at age 2-5 years residing in the metropolitan-Atlanta area. Children with ASD were identified from multiple schools and healthcare providers serving children with disabilities; children from the general population (POP) were randomly sampled from birth records. Recruitment was via mailed invitation letter with follow-up phone calls. Eligibility criteria included birth and current residence in study area and an English-speaking caregiver who could provide legal consent. Many children identified for potential inclusion could not be contacted. We examined demographic and perinatal factors associated with study completion using birth certificate data available for both participants and non-participants. Using the birth-certificate data, we also compared ASD-risk factor associations for the final sample of children who completed the study with the initial sample of all likely ASD and POP children invited to potentially participate in the study. Finally, we derived post-stratification sampling weights for participants who completed the study and compared weighted and unweighted associations between ASD and two maternally-reported factors collected post-enrollment.

Results: Maternal age >35 years and maternal education >12 years were independently associated with participation in the POP group. Maternal education >12 years was independently associated with participation in the ASD group. However, numerous other demographic and perinatal factors were not associated with participation. Moreover, unadjusted and adjusted odds ratios for associations between ASD and several demographic and perinatal factors were similar between the final sample of study completers and the total invited sample. Odds ratios for associations between ASD and maternally-reported reproductive health factors -- infertility and reproductive stoppage -- were also similar in unweighted and weighted analyses of the study completion sample.

Conclusions: We demonstrated empirically that while select demographic factors were directly associated with participation in a population-based case-control study of ASD risk factors, other demographic and biologic factors were not. Moreover, associations of biologic factors – both perinatal factors on the birth certificate and reproductive health history factors captured via maternal interview – were not impacted by differential participation. Additionally, while differential participation limited our ability to examine associations between ASD and two demographic factors – maternal age and education – this study demonstrated that the effect estimates for associations with several other demographic factors were unbiased. SEED is an important source of information on ASD risk factors. The findings from this analysis of GA SEED data indicate that the estimates from most SEED risk factor analyses are robust.

138 **184.138** Quantitative Autistic Traits Index Silently Transmitted ASD Risk across Generations

*M. V. Wong[1], D. Gray[2], N. Marrus[3] and **J. N. Constantino**[3], (1)Psychiatry, Washington University in St. Louis, St. Louis, MO, (2)Washington University in St. Louis, St. Louis, MO, (3)Washington University School of Medicine, St. Louis, MO*

Background: Multiple previous studies have demonstrated familial aggregation of quantitative autistic traits (QATs) in siblings and parents of individuals with ASD (Constantino et al, 2010, Lyall et al., 2014; Page et al., 2016).
Objectives: Here, we build upon the existing knowledge base via two new transgenerational studies examining the extent to which inherited behavioral phenotypes index causal influence for ASD.

Methods: The first transgenerational sample was comprised of epidemiologically-ascertained toddler twins and their parents. Measurement of QATs of parents and their children was implemented using the Social Responsiveness Scale-2 (SRS). Additionally, the toddlers were behaviorally phenotyped using eye-tracking measures of social visual engagement (SVE), which exhibit extremely high heritability and are strongly associated with the development of clinical autistic syndromes (Constantino et al., *Nature* 2017). In the second study, data from 150 multiplex ASD families enrolled in prior research were reviewed for transmission patterns strongly suspicious for silent maternal transmission of genetic risk, which is a putative mechanism for the so-called "female protective effect."

Results: Analyses in toddlers demonstrated that the biparental mean for QATs indexed by parental SRS scores predicted the SRS scores of their children at 36 months (r=.355, p<.001, n=142); heritability of the latter estimated from twin data was on the order of 0.85. Notably, QATs and SVE scores, based on total fixation time for looking at eyes, were uncorrelated (r=.037, p=.746) and equally heritable, indicating that SVE measurements constitute a separate quantitative behavioral phenotype indexing genetic risk for ASD.

In the second study, 15 of 150 multiplex families manifested an intergenerational transmission pattern in which all affected individuals were males and each mother of a son with ASD also had a male first degree relative (in her own generation or the preceding generation; i.e. among her brothers or father). Average SRS T-scores of such "suspected-silent-transmitter" mothers were 11 points greater than mothers in multiplex ASD families who did not fit this pattern of transmission, indicating a higher burden of autistic traits (t(9.3)=2.67, p=.025, effect size=.47) and corresponding to a raw SRS score 12 points greater than the general population mean. We note also that in an evolving prospective collection of second generation offspring of the sisters of males with ASD (who have previously been shown to manifest aggregations of sub clinical autistic traits), we have observed a rate of confirmed and suspected ASD in their male offspring of 24% in comparison to a rate of 10% in female offspring.

Conclusions: These data significantly expand upon the accumulated knowledge base on quantitative behaviors traits that index causal liability for ASD, and that might ultimately be utilized to identify females of childbearing age—particularly those in ASD-affected families—who are at elevated risk for silent transmission of ASD risk to their offspring.

139 **184.139** Recruitment Strategies for SPARK in Oregon

E. Fombonne[1], *L. D. Pacheco*[2]*, S. Mastel*[3]*, B. J. O'Roak*[4]*, L. Huang-Storms*[2]*, K. Headrick*[3] *and L. McMahan*[5]*, (1)Psychiatry, Pediatrics & Behavioral Neurosciences, Oregon Health & Science University, Portland, OR, (2)Oregon Health & Science University, Portland, OR, (3)Institute on Development and Disability, Oregon Health and Science University, Portland, OR, (4)Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, (5)Communications, Oregon Health and Science University, Portland, OR*

Background: Given the heterogeneity of the 'autisms,' very large sample sizes are required to research more homogeneous subgroups stratified by common clinical characteristics and/or by genetic profiles. Simons Powering Autism Research for Knowledge (SPARK) was launched in April 2016 with the goal of assembling a research cohort of 50,000 individuals with ASD recruited by 25 academic centers in the USA, including Oregon Health & Science University. The priority was set on recruiting trios (ASD individual + 2 biological parents) who can then be genetically characterized using whole genome sequencing.

Objectives: OHSU established a number of strategies to disseminate information and encourage ASD subjects and their relatives to sign up for this novel national registry. We targeted newly diagnosed/follow-up patients in the Autism Clinical Program (ACP-p), OHSU patients having a previous ASD ICD code in electronic medical records (OHSU-p), we connected and worked with community organizations, liaised with statewide special education professionals, ran local social media campaigns, and organized special events out of state (OOS) to reach out to a larger population base. Here, our objectives were to identify which recruitment strategies succeeded in achieving completed trio participation (completed registration process, self-reported phenotypic characterization, and successful collection of 3 saliva samples for ongoing genetic analysis).

Methods: Several metrics are regularly issued for each site including: 1) individual accounts created; 2) ASD probands having consented to genetic sample collection; 3) 'potential' trios (missing some consent data forms and/or biological samples); and 4) 'completed' trios (all trio data including usable biological specimen received centrally). Of note, some participants and trios may have joined SPARK without sites being properly credited for their recruitment.

Results: Over 18 months, 2,280 accounts were created and allocated to the OHSU site. Of these, 1,181 ASD probands did consent (or assent) for genetic analysis, including 963 children, 135 independent adults and 83 dependent adults. We could form 801 'potential' trios of whom 306 reached the final stage of full participation in SPARK. The process of registration lasted on average 110 days for 'completed' trios. The recruitment source for the 306 completed trios was: 33.2% for OHSU-p, 24.8% for OOS, 22.5% for ACP-p, and 19.5% for other sources. During the study period, approximately 375 patients were seen in the ACP for diagnosis/follow-up and individually targeted for SPARK participation. Less than 20% of those patients completed the registration despite repeated blast e-mails, systematic inclusion of flyers in family feedback sessions, banners posted in the hospital and in waiting rooms. By contrast, social media campaigns and out-of-state lectures/events accounted for a larger proportion of our recruitment (Figure). Recruitment analysis using other metrics and statistical models will be presented with longer run of data.

Conclusions: Considering Oregon epidemiological estimates (about 15,000 ASD subjects <20 years) and the pre-eminence of the OHSU ACP, relatively few ACP patients enrolled in SPARK. This is in marked contrast with research participation in other childhood diseases (e.g. cancer). Qualitative research to explore reasons for participation or not by our patient population is needed to address this gap.

140 **184.140** Testing the Limits of the SRS-2: Understanding Psychometric Limitations and How the Revised Short Form May Help in Some Ways

A. Kaat[1]*, C. Farmer*[2]*, V. Hus Bal*[3]*, A. Thurm*[2] *and S. Bishop*[4]*, (1)Nisonger Center, Columbus, OH, (2)National Institute of Mental Health, Bethesda, MD, (3)STAR Center for ASD & NDD; Dept of Psychiatry, University of California, San Francisco, San Francisco, CA, (4)University of California San Francisco, San Francisco, CA*

Background:

Because of its perceived dimensional, quantitative structure, the Social Responsiveness Scale (SRS; SRS-2) is widely employed in behavioral and biological studies of individuals with and without autism spectrum disorders (ASD). However, numerous studies have raised concerns that the degree of influence exerted by ASD-nonspecific factors like age, IQ, and behavior problems may affect the construct validity of the SRS. Recently, a short form of the measure was proposed (Sturm et al., 2017). Using an item response theory (IRT) approach, the authors determined that a shorter form may be a more valid unidimensional quantification of social-communication impairments. However, because this work combined samples of affected individuals and controls without testing key assumptions, it is possible that the item parameters were substantially biased. Further, additional evaluation in clinical samples is needed to determine whether short form scores successfully differentiate individuals with ASD from those with non-ASD diagnoses.

Objectives:

We sought to test the psychometric properties of the short form of the SRS proposed by Sturm et al. (2017).

Methods:

We used the IRT procedures employed by Sturm et al. (2017) to evaluate differential item functioning (DIF)-by-diagnosis in a subset of their data [affected individuals from the Simons Simplex Collection (n=2,630) and their unaffected siblings (n=2,273)]. We then evaluated the psychometric performance of the SRS short form in a clinically ascertained sample of children with ASD (n=670) or other neurodevelopmental disorders or psychiatric diagnoses (n=247), drawn from an existing databank (CADB/UMACC).

Results:

Initial examination of the *expected a posteriori* distribution revealed a multimodal distribution of the latent trait measured by the SRS short-form. The component distributions were not themselves normally distributed; although the proband distribution was relatively normal, the siblings comprised a zero-class and a right-skewed distribution. These results suggest that the short form is not valid for use as a quantitative measure in individuals *without* ASD. Further, we were unable to quantify DIF-by-diagnosis without eliminating further items from the SRS short form. In the clinical sample, children with (M±SD=28.58±8.57) and without (M±SD=18.23±9.88) ASD had significantly different SRS short form scores [F(1,890)=237.99, *p*<.0001]. Scores were moderately related to CBCL Internalizing (*r*=0.49, *p*<.0001) and Externalizing (*r*=0.41, *p*<.0001), and were not meaningfully related to nonverbal IQ (*r*=-0.15) or age (*r*=0.11). As previously documented with the SRS long form (Havdahl et al., 2016), children with significant emotional/behavioral problems who *did not* have ASD were indistinguishable from children *with* ASD but no other emotional/behavioral problems (*t*(471)=1.52, *p*=.13). Children with similar levels of emotional and behavioral problems were differentiated by the SRS short form (ASD versus non-ASD, *t*(471)=9.59, *p*<.0001). Further psychometric evaluation of the SRS short form in the clinical sample will be presented.

Conclusions:

As ASD symptoms are increasingly assessed in large-scale studies (e.g., ECHO), and as clinical psychology and psychiatry continue to ease reliance on categorical diagnoses, the appeal of quantitative instruments like the SRS becomes more apparent. However, to prevent misinterpretation, there is a clear need to understand more about the appropriate uses and limitations of this widely used tool.

141 **184.141** Time Windows of Exposure to Neonicotinoids in Parents of Autistic Children

E. Diamond[1] *and J. M. Diamond*[2,3]*, (1)The Wright Institute, Berkeley, CA, (2)Pediatrics, Kaiser Permanente, South San Francisco, CA, (3)Pediatrics, Kaiser Permanente Hospital, South San Francisco, CA*

Background:

Neonicotinoids were first synthesized in the 1980s and introduced into agricultural use and into pet products in the 1990s. Imidacloprid was the first neonicotinoid in widespread use. All are designed to target nicotinic acetylcholine receptors (nAChRs) and these are ubiquitous in humans as well as in insects. While differences between insect and mammalian receptors make them less acutely toxic to humans, effects of preconception and gestational exposures have been suspected. In particular, preconception exposures are understudied, even while the role of de novo (thus predominantly preconception) mutations in association with neurodevelopmental disorders has become increasingly apparent.

Our study nests within a larger study which asks parents of autistic children to answer questionnaires regarding geospatial exposure, health, occupational history, medication use, autism features and severity of their children.

Objectives:

Within our study population, we wanted to compare various time windows of in-home neonicotinoid exposure to each other. The five time windows studied are the three months prior to conception, the three trimesters of pregnancy and the three months postpartum.

Methods:

For broad outreach, we used social media to let parents know of the study. We invited birth mothers of autistic children to answer a questionnaire. Inclusion criteria were a diagnosis of ASD, child's birth in the year 2000 or later and valid consent. The questions regarding neonicotinoid exposure included imidacloprid-containing pet products for flea control. We felt mothers were likely to recall whether they were pet owners during pregnancy, and whether their pet received a flea product through application to the fur. We also asked about indoor pest control and home garden use. Lists of product names were supplied. Responses of "do not recall" or none were always options.

To analyze specific time window specificity of exposure, analysis was first restricted to those who reported exposure to a product in a single time window. We also analyzed exposures among the 32 possible patterns of multiple exposure. Importantly, here we are comparing time windows of exposure, with other time windows of exposure – not exposures of populations with and without autism.

Results:

The questionnaire was completed by 2212 mothers. For imidacloprid containing pet products, 670 (30.3%) recorded specific information regarding timing of exposure, of whom 242 recorded exposure in a single time window. Of these, 143 recorded exposure in only the pre-conception time window, 30 in the first trimester, 24 in the second trimester, 5 in the third trimester and 40 in the postnatal 90-day period. Importantly, this trend was also observed for other neonicotinoid home and garden exposures ($p < 0.001$).

Conclusions:

Our results show highest responses to exposures in the 90-day pre-conception time window. As parents are likely to share the same environment at the time of conception, paternal environmental exposures within this time period may be especially important since de novo mutations in autism are more frequently of paternal origin. Spermatogenesis takes place entirely within this time window. We believe neonicotinoids should be studied for their effects on gamete development in both sexes.

Poster Session
185 - Family Issues and Stakeholder Experiences
11:30 AM - 1:30 PM - Hall Grote Zaal

142 **185.142** A Qualitative Analysis of Psychological Strengths in Parents of Children with Autism Using the Five-Minute Speech Sample

A. L. Maughan *and J. A. Weiss, Psychology, York University, Toronto, ON, Canada*

Background: Despite growing recognition of the importance of taking a strengths-based approach to understanding families of children with autism (Bayat, 2007), research continues to focus on identifying, quantifying, and remediating deficits (Burnham Riosa et al., 2017). This negative focus extends to understanding parent-child relationships and parent functioning. The *Autism-Specific Five-Minute Speech Sample* (AFMSS) is a validated measure for this population that focuses on assessing expressed emotion in family members of children with autism (Benson, Daley, Karlof, & Robison, 2011). Expressed emotion in parents is an indicator of the degree of negative emotionality that is displayed when parents describe their child and the relationship they have with them (Morris, Silk, Steinberg, Myers, & Robinson, 2007). In contrast, the psychological processes of acceptance, mindful awareness and psychological flexibility, core concepts in the framework of Acceptance and Commitment Therapy (ACT; Hayes, Luoma, Bond, Masuda, & Lillis 2006), have been shown to be useful for understanding perspectives of parents of children with other chronic conditions (McCracken & Gauntlett-Gilbert, 2011). These strengths-based concepts in ACT may be relevant to observing positive change in parents of children with autism following intervention.

Objectives: The aim of this study is to assess change in parents' perceptions of their children with autism following participation in therapy, using the strengths-based concepts of acceptance, mindful awareness, and psychological flexibility.

Methods: Sixty parents of children with autism participated in cognitive behaviour therapy with their children. The AFMSS procedure, in which a parent is asked to speak about their child and the relationship they have with them for five uninterrupted minutes, was completed prior to and immediately post-intervention. Speech samples will be qualitatively analyzed using the interpretive phenomenological analysis approach (IPA; Smith, Jarman & Osborn, 1999), in which narrative data is coded for insights into participants' experiences and perspectives, and codes are catalogued and explored for themes. This approach will be used to identify strengths-based themes, including those related to acceptance, mindful awareness and psychological flexibility, and to observe and describe differences between pre- and post-intervention samples.

Results: Speech samples have been collected and transcribed, and qualitative data analysis is ongoing. Based on early data collection, emerging codes that can be identified related to ACT processes include: flexibly reframing their child's difficulties; awareness and insight into their child's emotions; and celebrating small improvements. These codes will continue to be catalogued and mined for overarching patterns or themes as analysis continues.

Conclusions: Results will be discussed in the context of evaluating interventions using a more positive understanding of strengths and change in a population whose experiences are typically only considered from a deficits perspective.

143 **185.143** Associations between Parenting Hassles and Depressive Symptoms in Hispanic and Non-Hispanic Mothers and Fathers of Children with Autism Spectrum Disorder

L. Nichols[1]*, N. Ekas*[2] *and M. Alessandri*[3]*, (1)University of Miami, Psychology, Miami, FL, (2)Texas Christian University, Fort Worth, TX, (3)University of Miami, Coral Gables, FL*

Background:

Parenting stress is associated with increased depressive symptoms in mothers and fathers of children diagnosed with Autism Spectrum Disorder (ASD), but mothers report higher levels compared to fathers (Ozturk, Ricadonna, & Venuti, 2014). The effects of everyday parenting hassles on parental mental health have not been studied. Parenting hassles may have varying effects on depressive symptoms across mothers and fathers. Furthermore, parents' perception of their quality of life is moderated by factors such as ethnicity (Schertz, Karni-Visel, Tamir, Genizi, & Roth, 2016). Thus, ethnicity may demonstrate similar moderating effects on depressive symptoms.

Objectives:

The goal of the current study was to examine whether parenting hassles were associated with depressive symptoms in mothers and fathers of children with ASD, and whether ethnicity (i.e., Hispanic versus Non-Hispanic) moderated this association.

Methods:

Participants included mothers and fathers of 117 children between 2 and 10 years of age with ASD (Hispanic M = 6.49, SD = 2.38; non-Hispanic M = 6.75, SD = 2.28). Participants were recruited from a regional autism center providing resources and support to families of children with ASD across the lifespan. Mothers' ages ranged from 20 to 55 (M = 38.33, SD = 6.05) while fathers' ages ranged from 30 to 62 (M = 41.96, SD = 6.53). Parents were assessed for depressive symptoms using the Center for Epidemiological Studies Depression Inventory (CES-D; Devins et al., 1988; Radloff, 1977). The Parenting Daily Hassles (PDH) scale assessed daily hassles. Although this measure has four subscales, only Frequency and Challenging Behavior subscales were used in this study (Crnic & Greenberg, 1990).

Results:

PROCESS macro moderation analyses were conducted in SPSS for mothers and fathers to determine the effect of parenting hassles, ethnicity, and their interaction on depressive symptoms. For mothers, increases in depressive symptoms were predicted by frequency of hassles (b= .35, t(244) = 5.82, p = .0000) and challenging behaviors (b = .65, t(241) = 6.69, p = .0000), but ethnicity was not a significant moderator of those symptoms (b= .0075, t(244) = -.18, p = .86; b = .00, t(241) = .0007, p = 1.00). In fathers, increases in the frequency of hassles predicted an increase in depressive symptoms (b = .25, t(153) = 3.75, p = .0003) as did increases in challenging behaviors (b = .63, t(144) = 5.07, p = .0000), but ethnicity was not a significant moderator (b = -.021, t(153) = -.47, p = .64; b = -.015, t(144) = -.18, p = .86).

Conclusions:

Frequency of parenting hassles and the presence of challenging behaviors predicted increases in depressive symptoms for both mothers and fathers of children with ASD. Although these associations were not significantly moderated by ethnicity, our findings suggests that parents, regardless of gender or ethnicity, are impacted negatively by everyday parenting-related hassles. These findings underscore the need to conduct further research aimed at better understanding the parental experience and developing interventions that effectively target these symptoms across diverse parent groups.

144 **185.144** Associations between Stress and Resourcefulness Among Parents of Children Exhibiting Risk for Autism Spectrum Disorder

M. Khowaja[1,2]*, D. L. Robins*[3]*, E. C. Tully*[1] *and L. B. Adamson*[4]*, (1)Georgia State University, Atlanta, GA, (2)Developmental Pediatrics, Children's Hospital Colorado, Denver, CO, (3)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (4)Psychology, Georgia State University, Atlanta, GA*

Background: Parents who are rearing children with a developmental disability have higher stress than parents raising typically developing children. Protective factors, such as optimism and social support, are associated with psychological well-being among parents of children with and without disabilities. However, little is known about when elevated stress among parents with developmental disabilities emerges; associations between parents' level of stress and resilience prior to their child's initial diagnostic evaluation has not been thoroughly researched. Resourcefulness refers both to internal processes to handle stress and external help-seeking behaviors that contribute to resilience. It is related to psychological adjustment in adults, but it has yet to be examined among parents whose children demonstrate risk for developmental disability. **Objectives:** This study utilizes a strengths-based approach to investigate associations between child functioning, parents' stress, and parents' resourcefulness just prior to an evaluation. In particular, this study sought to understand whether resourcefulness plays a buffering role against stress for parents.

Methods: The sample consisted of 119 parents of toddlers (mean age=21.0 months; *SD*=4.0) who demonstrated risk on an autism-specific screening questionnaire and had no prior DSM-5 diagnoses. Prior to the child's diagnostic evaluation, parents completed the Perceived Stress Scale and Resourcefulness Scale. During the evaluation, the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) was completed. Diagnostic outcomes included autism spectrum disorder (ASD; *n*=37), language disorder and other developmental disorder (DD; *n*=55), and no diagnosis (*n*=27). A moderation analysis was conducted to examine whether resourcefulness moderates the relation between child symptom severity (i.e., ADOS-2 comparison score) and parents' stress.

Results: Parent perceived stress levels measured before their child's evaluation were not significantly elevated (*M*=15.9, *SD*=7.5). Parent stress was significantly correlated with parent resourcefulness (*r*=-.267, *p*<.01). Moderation results indicated a significant moderating effect of resourcefulness on the relation between children's autism symptom severity and parents' stress, *b*=-.034, *SE*=.013, β=-.241, *p*=.009. Among parents with low levels of resourcefulness, high severity of autism symptoms was associated with high stress. Exploratory analyses examining ADOS-2 Social Affect subscale as the predictor also yielded significant moderation with significant simple slopes at both low (*b*=.977, *p*=.009) and high (*b*=-.839, *p*=.049) levels of resourcefulness. This demonstrates a buffering effect against stress associated with greater impairments in child social communication skills (i.e., having high resourcefulness may be a protective buffer). With ADOS-2 Restricted and Repetitive Behaviors score as the predictor in this model, the moderation was significant; however simple slopes were only significant at low levels of resourcefulness.

Conclusions: Although parent perceived stress levels were within normal limits, parents with low levels of resourcefulness may be vulnerable to stress related to severity of child's very early symptom presentation. However, greater resourcefulness may be a protective factor against parent stressors associated with their child's impairments in reciprocal social interaction and communication skills in particular. In the future, screening parents at risk for elevated stress and poor mental health functioning during the diagnostic evaluation of their child's developmental disability may be helpful to promote positive well-being in parents after diagnosis of their toddler.

145 **185.145** Autistic People's Perspectives on Stereotyping: An Interpretative Phenomenological Analysis.

C. Treweek[1]*, C. Wood*[2]*, J. Martin*[2] *and M. Freeth*[3]*, (1)The University of Sheffield , Sheffield , United Kingdom of Great Britain and Northern Ireland, (2)Psychology, The University of Sheffield, Sheffield, United Kingdom, (3)Psychology Department, University of Sheffield, Sheffield, United Kingdom*

Background:
Autistic stereotypes are on the most part negative, where autistic people are perceived as having a number of negative traits such as being: disruptive and distracting to others (White, Hillier, Fry & Makrez, 2016), unsocial, quiet and emotionless (Harnum, Duffy & Ferguson, 2007). The only exception to this is the autistic savant, where autistic people are seen as having superior abilities in specific domains (Draaisma, 2009; Conn & Bhugra, 2012; Tang & Bie, 2016; Anjay, Palanivel & Palanivel, 2011). However, there is a paucity of research that has looked at how autistic people think they are perceived by others, and no studies to date have asked autistic people what they think the autistic stereotypes are.

Objectives:

This study examined how autistic people felt they are perceived by others, including what the autistic stereotypes are from their perspectives and lived experiences.

Methods:

A qualitative design was chosen, consisting of semi-structured interviews, and a set of pre-prepared questions that had been piloted beforehand with autistic people. 12 participants were interviewed and their responses were tape recorded (*M*=28 minutes) and then transcribed verbatim. Transcripts were analysed using Interpretative Phenomenological Analysis (IPA) (Smith, Flowers and Larkin, 2009), which involved coding each script for linguistic content, descriptive content and interpretation of possible meanings, resulting in a list of themes for each individual participant. A set of recurrent master themes was then identified across the whole data set. In order for a theme to be classed as recurrent, it needed to be present across at least half of participants. To ensure credibility of the analysis a subset of scripts were checked for accuracy and quality of interpretation by one of the co-authors.

Results:

Four master themes emerged from the analysis of the data. These were: (1) Autistic people are 'weird', (2) Negative effects/consequences of autistic stereotypes, (3) Heterogeneity of autistic people, (4) The effect of the environment / context. Most participants thought that autistic people may be perceived by others as being 'weird'. Finding also demonstrated that being perceived in a negative way by others may lead to negative consequences for autistic people - such as bullying and exclusion. The diversity of people on the autistic spectrum was also emphasised by participants, especially in relation to the range of traits both stereotypic and counter-stereotypic (atypical) that autistic people can have.

Finally participants highlighted how certain environments be both disabling and enabling for autistic people.

Conclusions:

Participants in this study felt they were being perceived in a predominantly negative way and that this may have negative outcomes for autistic people. This finding is important as negative attitudes towards others can lead to negative behaviour, if left unchallenged. Moreover, this study highlights the diversity of autistic people and challenges stereotypes that autistic people are all the same. Finally this study highlights the importance of creating environments that do not limit or disable autistic people in any way.

185.146 Behavioral Artistry: Validation of Preferred Characteristics of Effective Behavioral Interventionists in Autism By Parents and Practitioners

K. Callahan[1], *R. L. Foxx*[2], *S. M. Nichols*[3], *S. Mehta*[4], *R. Sharma*[5], *X. Aerts*[3], *A. Swierczynski*[6], *M. E. McComb*[3], *K. Flatt*[1], *G. Segal*[3] *and W. Mackey*[1], *(1)University of North Texas, Denton, TX, (2)Penn State University at Harrisburg, Harrisburg, PA, (3)Kristin Farmer Autism Center, University of North Texas, Denton, TX, (4)Educational Psychology, University of North Texas, Denton, TX, (5)Rehabilitation and Health Services, University of North Texas, Denton, TX, (6)University of North Texas Kristin Farmer Autism Center, Denton, TX*

Background: The article “Twenty-five years of Applied Behavior Analysis: Lessons Learned” summarized insights from three decades of research and treatment in the field of Applied Behavior Analysis, concluding that the effectiveness of ABA therapy may be negatively impacted by limited skillsets among today’s behavioral interventionists. Richard Foxx believes there is an important difference in outcomes between persons delivering ABA services in a traditional way (“behavioral technologists”) and those who demonstrate a broader set of humanistic/interpersonal behaviors (“behavioral artists”). Behavioral technologists often simply deliver a scripted set of procedures without a focus on the quality of the interaction. In contrast, behavioral artists demonstrate eight characteristics which mark these therapists as “natural behavior analysts,” including having a sense of humor, using effective communication skills, and being caring, flexible, and optimistic.

Objectives: We investigated Foxx’s conclusion that behavioral interventionists today lack important interpersonal behaviors associated with BA when compared to service providers in other human services professions, and whether parents of children with autism, and other service providers, prefer characteristics associated with behavioral artistry: (1) Can BA characteristics be correlated with validated standardized assessments?; (2) What are the relationships between self-reported characteristics of BA and students majoring in Behavior Analysis, Special Education, Rehabilitation Studies, Other Human Services majors, and Engineering/Computer Science?” and (3) What is the level of social validity of BA characteristics by parents of children with ASD?

Methods: We reviewed psychological assessments in order to correlate operationally-defined BA traits. Expert raters (N=38) determined that Cattell’s Sixteen Personality Factor Questionnaire (16PF) correlated significantly with BA traits. An online 16PF survey was completed by more than 200 university students in the target majors, many of whom currently provide services for individuals with autism at a university-based treatment center. ANOVA and other statistical analyses were conducted to determine differences between levels of BA reported by undergraduate and graduate students in the various majors. An online survey was completed by a national sample of parents (N=86) of children with ASD. Parents read descriptions of characteristics of autism service providers and chose preferred traits. Responses were analyzed to determine the level of social validity for the correlated BA traits.

Results: Students majoring in behavior analysis reported a lower percentage of BA traits than those in all other human services majors. Parents of children with autism preferred the 16PF factors associated with BA traits over non-BA traits for 14 of 15 traits.

Conclusions: These results provide face and concurrent validity for the concept of BA as a potential factor in the delivery of improved treatment in autism. Social validation of BA was demonstrated by clear parent preferences for the traits associated with BA by behavior analysts and interventionists. However, our results indicate that behavioral interventionists in the field of autism may lack many important clinical/interpersonal skills. Research is underway to determine if interventionists with lower rates of BA implement treatment less competently and if they have less positive outcomes. This research could have significant implications for the preparation and training of effective service providers in autism.

185.147 Broader Autism Phenotype Characteristics and Young Adults' Sibling Support

A. Jensen[1] *and G. I. Orsmond*[2], *(1)Brigham Young University, Provo, UT, (2)Department of Occupational Therapy, Boston University, Boston, MA*

Background: Despite less frequent contact than at younger ages (e.g., White, 2001), young adults’ relationships with their siblings have important implications for relational and individual adjustment (e.g., Jensen et al., 2013). Given that siblings play important roles, as parents age, in caring for siblings with an autism spectrum disorder (ASD; Burke et al., 2012), it is critical to understand the nature of how young adult siblings support one another. In particular, examining how Broader Autism Phenotype (BAP) characteristics are associated with sibling support may aid in understanding these processes.

Objectives: The aim of this study was to examine associations between BAP characteristics in both young adults and their siblings, and the support young adults provide their siblings. Because of the gendered nature of sibling relationships and support (Kim et al., 2006), we examined whether patterns of support varied by young adults’ and their siblings’ sex.

Methods: Data came from a larger study about sibling influence in young adulthood, which included 873 young adults from across the United States, recruited through Amazon Mechanical Turk. Young adult participants were in their mid 20s (*M age* = 25.44, *SD* = 2.54) and had about two siblings (*M* = 2.23, *SD* = 1.49), were mostly female (56%), and Caucasian (73%). Participants reported their relationship with their closest aged sibling and up to two additional siblings (if applicable). In total, the 873 participants reported on tangible (financial and practical) and emotional (communication, discussing life, emotional assistance) support with 1,543 different siblings. Participants reported on their own BAP characteristics and those of each of their siblings via the Autism Spectrum Quotient (AQ; Baron-Cohen et al., 2001); 10 of the young adults and 27 of their siblings were reported to have a diagnosed ASD.

Results: Multi-level modeling was used to account for the nature of multiple relationships being nested within individuals. Separate hierarchical models were run for each dependent variable: tangible support, and emotional support. The models tested up to the three-way interactions of the young adults’ BAP characteristics X young adults’ sex X siblings’ sex, and the siblings’ BAP characteristics X young adults’ sex X siblings’ sex. Results revealed (see Table 1) that when young adults rated their sibling higher on the AQ, they reported giving more tangible support to that

sibling, especially towards brothers. Females who rated themselves higher on the AQ also reported giving less tangible support to their brothers and sisters. Results also revealed (see Table 2) that individuals who rated themselves higher on the AQ reported giving less emotional support to their brothers and sisters.

Conclusions: These findings suggest that BAP characteristics in the general population, and not just ASD diagnosis, may play a role in the support siblings provide one another in young adulthood. In some cases, siblings may be aware of the needs of their brothers and sisters who show characteristics associated with ASDs, and may provide more tangible support to them. Those who report having more BAP characteristics themselves may not support their siblings in return

148 **185.148** Building Bridges between the Autism and Research Communities: Opinions from People with a Lived Experience of Autism

D. Poole[1], *E. Gowen*[2], *A. Greenstein*[3], *T. Bleazard*[4], *P. Baimbridge*[5], *J. T. Pelham*[6] *and K. Stevenson*[6], *(1)Division of Neuroscience and Experimental Psychology, University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (2)Division of Neuroscience and Experimental Psychology, University of Manchester, Manchester, United Kingdom, (3)Manchester Metropolitan University, Manchester, United Kingdom, (4)University of Manchester, Manchester, United Kingdom, (5)Salfordautism, Salford, United Kingdom, (6)Non-Affiliated, Manchester, United Kingdom*

Background: Recent work has highlighted that there is a disconnect between the autistic and research communities (Pellicano, Dinsmore & Charman, 2014ab). There is a concern that this is harming trust, leading to the reduced involvement of autistic people in research and skewing research priorities. It has also been suggested that research is failing to impact the everyday lives of the majority of autistic people.

Objectives: In the present study, we sought the opinions and experiences of the autism community about research in an attempt to improve mutual understanding and identify how the academic and autism communities could work together better.

Methods: The project involved a collaboration between Autism@Manchester, an interdisciplinary network including academics from several research fields and Salfordautism, an autism support organisation that is led and run by autistic people. We organised 3 x 2 hour workshops with autistic adults and the parents of autistic children (n = 30). The workshops included (1) introducing the group to different types of research (2) focus groups exploring experiences of research, barriers to research participation and possible solutions (3) possibilities for future partnerships. Here we outline the focus group results, analysed using thematic network analysis.

Results: Three overarching themes were identified in analysis of the focus group discussions. The first theme explored motivations for taking part in research. Participants highlighted a desire to learn about themselves and improve society's understanding of autism. Research participation was highlighted as a valuable form of post-diagnostic support. However, participants expressed a desire to shape research goals, moving beyond passive participation. The second theme explored ways of equalising power relations between participants and researchers. Participants criticised a failure to share research outcomes quickly and in accessible forms. Forums for discussing research findings were highlighted as crucial for building bridges. In the third theme, practical advice for involving the autistic community in research was considered. Participants expressed a broad desire for more participation and suggested linking research networks to reduce the work in finding out about opportunities to participate. Ways to improve accessibility and the dissemination of research information were also addressed. Several ongoing challenges to greater involvement of the autism community in research were also identified including lack of institutional support and the different ways in which autistic and non-autistic people express themselves.

Conclusions: There was a strong positive view about research with participants understanding and supporting its value. Our focus group analysis showed that engagement was necessary throughout the research process. From study design to implementation, dissemination and discussions moving forward, the autism community suggested opportunities for facilitating participation and increasing partnership. These findings have been written into guidelines aimed to support autism researchers to build stronger partnerships with the autism community for successful research in future.

149 **185.149** Characterising the Relationship between Maternal Sleep, Child Daytime Behaviour and Physical and Mental Wellbeing in Mothers of School-Aged Children with and without a Diagnosis of Autism

Z. Yusuf[1], *G. Pavlopoulou*[2], *D. Dimitriou*[3] *and W. A. Bin Eid*[4], *(1)Lilas Lab UCL IOE, London, United Kingdom, (2)Lifespan Learning and Sleep Lab, UCL.IOE,Lilas Lab, london, United Kingdom of Great Britain and Northern Ireland, (3)Lifespan Learning and Sleep Laboratory (LILAS) UCL, Institute of Education, London, United Kingdom, (4)Lifespan Learning and Sleep Lab, Institute of Education UCL, London, United Kingdom*

Background: Raising a child with autism brings unique opportunities and challenges. Over the past 20 years a growing body of research has been examining the role of autism severity and child behaviours on maternal wellbeing. Sleep problems are very common in children on the autism spectrum and in other members of their families. Those sleep problems include difficulty falling asleep, waking during the night, erratic/irregular sleep patterns, other arousals/disturbances, and daytime sleepiness. However, we still know very little we know about the relationship of sleep, maternal wellbeing and child behaviour.

Objectives: This study aims to characterise the relationship between maternal sleep, chid daytime behaviour and physical and mental wellbeing in mothers of school-aged children with and without a diagnosis of Autism.

Methods: A cross-sectional, mixed design was employed. 40 mothers completed a number of psychometric self-reports, a questionnaire on autism severity and child daytime behaviours as well as a a 7-day sleep diary.

Results: A self-selected sample of 20 mothers raising a child with a diagnosis of autism and 20 mothers of typically developing children were recruited from various community settings and charities in the UK. Mothers with a child with an autism diagnosis reported poorer sleep (M= 9.00), higher parenting stress, (M= 95.30) lower physical quality of life (M= 47.19) and emotional quality of life (M= 40.30) than mothers of typically developing children. Maternal stress (p = .014) and emotional quality of life (p = .005) were significant predictors of child behaviour problem in mothers of children with autism.

Conclusions: This is one of the very few studies aiming to characterise the relationship between sleep and wellbeing in the life of mothers with a child with autism. Implications of this research shed light in areas that healthcare practitioners should consider the effects of sleep in all family members when looking for interventions targeting quality of life. Further research should employ non-invasive objective sleep measures such as actigraphy along with interviews to gain better insights into their sleep patterns and hygiene and verify links with physical, mental health and overall quality of life.

150 **185.150** Characterising the Relationships between Sleep Patterns, Anxiety Profiles, School Attendance and Daytime Behaviour in Female Adolescents with and without a Diagnosis of Autism

N. Ready[1]*, G. Pavlopoulou*[2] *and D. Dimitriou*[3]*, (1)Lilas Lab UCL IOE, London, United Kingdom, (2)Lifespan Learning and Sleep Lab, UCL.IOE,Lilas Lab, london, United Kingdom of Great Britain and Northern Ireland, (3)Lifespan Learning and Sleep Laboratory (LILAS) UCL, Institute of Education, London, United Kingdom*

Background: There is a wealth of literature for the role sleep plays in the growth, development, health and well-being of adolescents. In recent years, research in gender and autism has developed at pace, developing our understanding of the way autism needs present in females and the challenges they experience as a result of this. This field is still, however, widely under-researched.
Objectives: To examine the role sleep plays within female adolescents and the influence it has on anxiety and daytime behaviours, both at home and at school.

Methods: Using a multi-informant research design, including both subjective and objective sleep measures, a cross-sectional, quantitative, correlational study examining the relationships between sleep patterns, anxiety profiles, school attendance and school behaviours in typically developing female adolescents and female adolescents with autism was carried out. Actigraphy data were collected, alongside self-report (Pittsburgh Sleep Quality Index, Beck Youth Inventories II, Strengths & Difficulties Questionnaire), parent-report (Child Sleep Habits Questionnaire, Strengths & Difficulties Questionnaire) and teacher report (Strengths & Difficulties Questionnaire, Child Behaviours Checklist) questionnaires for anxiety and behaviour. School attendance information was also collected.

Results: 33 female participants (16 without a diagnosis; 17 with a diagnosis), between 11-16 years of age, completed the study. Sleep patterns in isolation were broadly similar between both groups and all participants were getting 2-4 hours less than the 2017 National Sleep Foundation recommendations. However, differences were found between the two groups, between sleep patterns and each of the outcomes examined with a significant number of correlations found between these factors in female adolescents with autism. In females with a diagnosis of autism, positive correlations were found between self-reported anxiety and sleep disturbances. Anxious behaviours were reported by parents to increase as the scores in each sleep domain increased also. A linear regression demonstrated that each of the following sleep domains significantly predicted the total difficulties in behaviours score reported by parents of females without a diagnosis in the SDQ, accounting for a significant proportion of the variance found in parent reported behaviour scores. Sleep anxiety also significantly predicted the total difficulties score reported. For teacher reported behaviours in females with a diagnosis, the most frequent negative correlations occurred also with actigraphy mean bed time, indicating the importance of this factor across both groups of participants.

Conclusions: These findings have implications not only for parents and professionals in considering the impact of poor sleep patterns on outcomes at home and school, but also for developing adolescents' awareness and understanding about the important role sleep plays in their wellbeing. Future research should examine sleep patterns and sleep hygiene using subjective sleep measures and eliciting personal account on sleep to understand in more depth the relationship between sleep

151 **185.151** Considering Methodological Accommodation to the Diversity of ASD: A Realist Synthesis Review of Data Collection Methods

J. D. Orjasaeter[1]*, D. B. Nicholas*[2] *and L. Zwaigenbaum*[3]*, (1)Faculty of Social Work, University of Calgary, Central and Northern Alberta Region, Edmonton, AB, Canada, (2)University of Calgary, Edmonton, AB, Canada, (3)University of Alberta, Edmonton, AB, Canada*

Background:
Qualitative inquiry related to the lived experiences of ASD is shown as largely drawing on traditional approaches; most notably, interviews and focus groups (Tesfaye, 2016). These approaches potentially limit data elicitation from subpopulations within ASD such as individuals with co-existing cognitive and/or communicative challenges. Such subgroups potentially have unique experiences that merit greater understanding. Methodological adaptation appears needed to incorporate a more flexible range of research approaches. To fail to do so risks errors of commission (e.g., presumption of data validity) and omission (e.g., missed sub-group representation of experience).

Objectives:
The aim of this umbrella review was to identify potential and promising approaches to data collection that could ensure more inclusion and accommodation of the range of ASD expression. Drawing on a realist synthesis approach, this review explored the following research question: "What data collection approaches inform the assessment of lived experience across the breadth of cognitive and communicative abilities and expression in ASD?".

Methods:
This realist synthesis review intentionally included relevant yet disparate substantive areas, populations and contexts to amplify potentially salient understanding. Data collection methods elicited lived experience or first person accounts of populations with variable levels of language and cognitive expression. Articles were reviewed, identified and coded.

This review drew on three relevant yet distinct literature bases and populations: (i) persons with ASD, (ii) persons with intellectual disability, and (iii) persons with dementia. Selection of these diverse disability areas and populations accounted for an inherent range of inter- and intra-population abilities/disabilities and experiences which included domains of language expression, communication and cognition.

Results:
The overall search yielded a total of 1,244 studies; 162 studies were confirmed to be eligible for inclusion. Studies meeting inclusion criteria represented a variety of research designs that consisted of exploratory, descriptive and evaluative research. Common methods in studies included interviews, focus groups, observation, surveys, standardized assessments and inventories. Methods that were viewed to be salient to the application of strategies for eliciting first-hand perspectives included photovoice (n= 6 studies), Talking Mats (n= 2 studies), 'deep assessment' (n= 1 study), SenseCam (n= 2 studies), and TimeSlips (n= 2 studies). These approaches identify potential methods for more inclusive engagement in studies than traditionally may have been accommodated.

Conclusions:

Findings from this review inform person-centered research in the aim of eliciting depth and breadth of diverse lived experience and first-person expression in ASD. Emerging evocative approaches offer methodologic possibilities, yet may impose challenges based on data conformity and a lack of clearly defined methods for the ASD population. Notwithstanding such challenges, optimal data yield warrants careful consideration relative to the important aim of inclusive representation in ASD sampling. Addressing these considerations have the potential to advance knowledge about first person experiences and needs of people with ASD and in so doing, move the research community beyond conventional methods in the aim of inclusive ASD research.

152 **185.152** Coparenting and Well-Being in Mothers and Fathers of Children with Autism Spectrum Disorder

***N. Ekas**, Texas Christian University, Fort Worth, TX*

Background: Fathers of children with autism spectrum disorder (ASD) have been relatively neglected in research; however, recent research has investigated the quality of the coparenting relationship and its association with parental well-being (May, Fletcher, Dempsey, & Newman, 2015). Parents of children with ASD typically have lower levels of well-being and romantic relationship quality (Gau et al., 2012). However, a positive coparenting relationship beneficially impacts well-being (May et al., 2015). One factor that may influence the quality of the coparenting relationship are parental perceptions of the father's role in raising his children (Schoppe-Sullivan et al., 2008).

Objectives: The purpose of this study was to examine associations between perceptions of the father's role, coparenting relationship quality, and well-being in mothers and fathers of children with ASD.

Methods: Thirty-three cohabitating couples of a child with ASD (age 4–12) completed online questionnaires to assess perceptions of the role of the father (ROFQ), the quality of the coparenting relationship (CRS), depressive symptoms (CESD), and romantic relationship satisfaction (CSI).

Results: For fathers, coparenting closeness mediated the relationship between paternal perceptions of the role of the father and depressive symptoms (95% CI: -.69, -.01) and relationship satisfaction (95% CI: .05, 3.34). Greater perceptions of the role of the father were associated with greater coparenting closeness, $b = .07$, $SE = .04$, $p < .05$, which was associated with fewer depressive symptoms, $b = -2.81$, $SE = 1.19$, $p < .05$, and higher romantic relationship satisfaction, $b = 15.72$, $SE = 2.75$, $p < .001$. For mothers, coparenting closeness also mediated the relationship between maternal perceptions of the role of the father and depressive symptoms (95% CI: -.92, -.08) and romantic relationship satisfaction (95% CI: .67, 3.26). The pattern of associations was similar to that for fathers.

Conclusions: This study provides preliminary evidence that the coparenting relationship is associated with better individual well-being and better dyadic well-being. Although studies have yet to investigate the role of the father in the context of ASD, it appears that both mothers and fathers believe that the father has an important role, which allows them to not only be closer as parents but also as a couple. Therefore, interventions could help enhance perceptions of a father's role to encourage a positive coparenting relationship in order to benefit well-being.

153 **185.153** Decision-Making Processes That Inform Parents' Disclosure of Their Child's Autism Diagnosis to Others

***S. Thompson-Hodgetts**[1], L. G. Rogers[1], R. Mazumder[1] and S. K. Phelan[2], (1)University of Alberta, Edmonton, AB, Canada, (2)Occupational Therapy, University of Alberta, Edmonton, AB, Canada*

Background: When children are diagnosed with ASD, parents are faced with numerous decisions, including to whom they should disclose this information. There are limited resources to inform their decisions and no literature that looks at processes of disclosure.

Objectives: To investigate the decision-making processes by which parents of a child diagnosed with ASD choose to disclose their child's diagnosis to others; for example, educators, family and friends, healthcare professionals, other parents, and others in the community.

Methods: In this constructivist grounded theory study, we conducted semi-structured interviews with 25 parents (19 mothers, 6 fathers) of 23 children diagnosed with ASD (19 males, 4 females, age range 3 to 13 years). Participants were purposefully sampled across diversity in child age, presentation across the ASD spectrum, time since diagnosis, and decisions to disclose or not disclose. Interviews were transcribed verbatim and managed through NVivo 11 Pro. Established grounded theory constant comparison methods were used to yield processes depicting parents' decision-making related to disclosure of their child's ASD diagnosis to others. Following convention in qualitative research, rigor was demonstrated through established methods of trustworthiness and authenticity, including critical reflexive dialogue with colleagues about the data, prolonged engagement by team members immersed in ASD, negative case analysis, and member-checking through clarification probes during interviews.

Results: Five sequenced processes informed disclosure: (1) Finding the Fit (2) Assessing the Benefits, (3) Following Values and Beliefs, (4) Managing Peoples' Responses, and (5) Adjusting Along the Way. Parents initially needed to determine whether the diagnosis of ASD was a fit for their child, which involved learning about or changing their perceptions about the disorder, as they typically did not know a lot about ASD. The primary reason for disclosure to anyone was whether it would benefit the child for others to know the diagnosis. All parents disclosed to the school with the expectation that the child would receive services and understanding. A secondary consideration was whether disclosure supported the parent. Next this information was filtered through the parents' values and beliefs related to privacy, disability, and family culture. These were rarely black and white decisions, and often parents disclosed to some people and not to others. Parents needed to then manage the varying responses and advice from others. Then, as the parent and child journey continued, decisions to disclose or not disclose sometimes changed based on responses from others.

Conclusions: The process of disclosing their child's diagnosis of ASD to others is complex. Findings from this study can contribute to discourses related to disclosure or non-disclosure, and help increase sensitivity and understanding for healthcare professionals, educators, and the general public related to parents' decisions of whether or not to disclose their child's diagnosis of ASD.

154 **185.154** Expecting Family Members to be on Board: Parents' Disclosure of Their Child's ASD Diagnosis to Relatives

***S. Thompson-Hodgetts**[1], L. G. Rogers[1], R. Mazumder[1] and S. K. Phelan[2], (1)University of Alberta, Edmonton, AB, Canada, (2)Occupational Therapy, University of Alberta, Edmonton, AB, Canada*

Background: Parents who receive a diagnosis of ASD for their child are faced with immediate and ongoing decisions of who to inform about the diagnosis. There is little in the literature to support parents in making these disclosure decisions, and to inform professionals who often support parents in these decisions.

Objectives: To investigate why, when and how parents disclosed their child's autism diagnosis to others, including both the decision-making process as well as the impact of these disclosure decisions. This abstract represents the results of disclosing the ASD diagnosis to relatives.

Methods: A constructivist grounded theory design was used. Grounded theory is well established for the investigation of complex, multi-faceted human experiential phenomena, offering a theoretically rich understanding of processes and perceived outcomes. We interviewed 25 parents of children diagnosed with ASD across Alberta, Canada. Our diverse sample included 19 mothers and 6 fathers (aged 28-56 years) of 23 children (19 males and 4 females, aged 3 to 13 years). Children were diagnosed between one month and eight years prior to the interview. Five participants indicated they immigrated to Canada, away from their relatives. Interviews were transcribed verbatim and managed through NVivo 11 Pro.

Results: Parents reported various criteria and factors that affected why, when and how they disclosed their child's ASD diagnosis to their relatives. While some parents told all family members, many had a more mixed profile of reporting to some relatives and not others. Factors affecting disclosure included the relationship, age, and geographic distance from relatives; how much contact they had with relatives on a day-to-day basis; and whether disclosing diagnosis to a relative offered perceived benefit to the child or parent. Parents rarely disclosure to their elderly parents or those who were geographically distant if they thought the diagnostic information would worry them. Results of disclosure were complex. Participants' reported that relatives' responses ranged from many who received support and acceptance by relatives, to well-meaning but not helpful responses from relatives, denial of the diagnosis, lack of understanding of ASD, and imposing judgment on the parents for poor parenting and family genetics. Further complicating the disclosure process were cultural and societal factors of stigma and blame which were imposed on the parents from relatives and others. More complex interactions were also described including the parents and relatives coming to terms with recognition of a potential ASD diagnosis among family members including spouses. Couples often differed in preferences for disclosure to relatives, but, except in a few cases, this lack of agreement was not reported as a source of conflict; often parents would agree that one parent take the lead in the disclosure process.

Conclusions: The processes involved in disclosing the diagnosis of ASD to relatives are complex. In many cases relatives were available to support parents, but in other cases relatives became a source of additional worry and stress for the parents at a time when they desired support.

155 **185.155** Early Intensive Parent Training to Promote Development of Their Children with Autism Ameliorates Anxiety & Marital Discord and Increases Knowledge of Autism

B. Siegel[1], *S. Behar*[2] *and R. DeWitt*[3], *(1)Autism Center of Northern California, San Francisco, CA, (2)Palo Alto University, Palo Alto, CA, (3)Autism Center of Northern California (ACNC), San Francisco, CA*

Background: This study focuses on the effects of parent training on parental well-being. Parenting a child with autism is an unanticipated life stressor managed alongside the goal of optimizing benefit to the child. Various approaches to parent training have emerged to 1) bolster and generalize the effect of professional child interventions for autism, 2) manage a child's problem behaviors, and 3) teach communication skills. There is, however, less study on how parent training may improve parent well-being. We test the idea that parents with a greater knowledge of autism, and with technical skills to develop daily living skills, communication, social and play skills will have fewer negative psycho-social outcomes than parents who do not undergo early training to acquire these knowledge and skills.

Objectives: The present study was to compare knowledge of autism and measures of psychological well-being in parents who did and did not receive a full-time, week-long 1:1 intensive parent training protocol shortly after diagnosis of autism in their 2-3 year old. This preliminary cross-sectional study was carried out as a first step in longitudinal examination of adjustment to the diagnosis of autism in parents. We intend to examine the bi-directional influence of child improvements in parent outcomes alongside effects of parent training in improving child outcomes. We see characterization of bi-directionality as important in understanding how to help parents adjust to the diagnosis of autism, especially given some children will not improve as markedly as others. It is logical that parents with a child who improves markedly to feel better; but how do we also help parents who may need to adjust expectations? What are factors in supporting such parents to feel comparably successful when they are just as active and well-trained as caregivers?

Methods: The treatment group attended week-long, 30-hour parent training with one-to-one demonstrations and coaching from behavioral, communication, and play and social skills intervention specialists. Study respondents completed *Knowledge of Autism*, and *Adjustment to the Diagnosis of Autism* (ADA) questionnaires, plus the *Beck Depression Inventory (BDI)* and the *Dyadic Adjustment Scale (DAS)*. The current N=12 for the intervention group, with the aim of a matched non-treatment group by INSAR.

Results: Intervention group parents showed 79% accuracy in their knowledge about autism. On the *BDI*, they showed less than average anxiety (45th percentile). On the *DAS*, respondents indicated they most always agreed on external family issues (50th percentile), had only occasional problems on more intimate topics (82nd percentile), having positive interactions at least once per day. On *ADA* intervention group parents showed they accepted the diagnosis and felt others should know more about autism, noting they believed they would feel better as their child did better, and that reading all you can was a helpful coping strategy.

Conclusions: Our preliminary data on trained parents suggest fairly low levels of anxiety, fairly good levels of understanding about autism, as well as adequate scores on psychosocial measures. Our presentation in May will contrast these results to parents who have not (yet) received the same parent training.

156 **185.156** Elucidating Female Autism Study (EmFASiS). Investigating Differences in Presentation, Diagnostic Process and Personal Experiences in Males and Females with Autism.

S. Piening[1], *Y. Groen*[2], *K. Greaves-Lord*[3], *S. Castelein*[4,5], *A. F. Stapert*[1], *A. M. Euser*[1], *D. Jansen*[1], *L. Davids*[1,6] *and I. D. van Balkom*[1,7], *(1)Autism Team Northern Netherlands, Jonx (Lentis), Groningen, Netherlands, (2)Clinical and Developmental Neuropsycholog, University of Groningen, Groningen, Netherlands, (3)Erasmus MC, Rotterdam, Netherlands, (4)Lentis Research (Lentis), Groningen, Netherlands, (5)Experimental Psychotherapy and Psychopathology, Behavioural and social sciences, Rijksuniversiteit Groningen, Groningen, Netherlands, (6)Medical Psychology, Martini Hospital, Groningen, Netherlands, (7)Lentis Psychiatric Institute, Zuidlaren, Netherlands*

Background:

Females are more often affected by Autism Spectrum Disorder (ASD) than previously assumed. Differences in ASD symptoms and complaints, and male-biased diagnostic instruments combined with better skills in masking ASD-symptoms by females may contribute to late recognition of symptoms. Females with late diagnosed autism often look back with sadness when considering how different their lives could have been had they received a timely diagnosis and appropriate care.

Objectives:

The **E**m**FAS**i**S** project consists of several studies and this first study aims to facilitate earlier identification and diagnosis of ASD in females through better understanding of female autism phenotypes and differences with males. Improved understanding of autism in females will inform diagnostic and treatment processes and may prevent emergence of comorbid disorders, and unexplained physical symptoms. Issues which lead to lower quality of life, decreased participation in society, and higher societal costs.

Methods:

The first study of the **E**m**FAS**i**S** project consists of semi-structured interviews with 15 females and 15 males with autism. The semi structured interview will be developed in close cooperation with experienced service users and will include questions regarding experiences with their gender-roles (such as daughter/son, friend, partner, parent, caretaker, employee), current and past complaints and symptoms, as well as personal diagnostic process and treatment. Analyses will be performed using a qualitative data-analysis program.

Results:

The study will start in December 2017 and results of the qualitative study will be presented at the conference.

Conclusions:

In addition to gaining insight into differences in presentation, diagnostic process and personal experiences in males and females with autism, we expect to identify influencing factors regarding diagnostic delay in females.

157 **185.157** Evaluating Depression and Quality of Life in Mothers of Children with Autism Spectrum Disorders

*A. Deshpande[1], P. Sunil[2], M. Bhargavi[1], D. Murnal[2], N. Mundkur[2] and **A. Jayaraman**[3], (1)Sangamitra, Bangalore, India, (2)Centre for Child Development and Disabilities, Bangalore, India, (3)Center for Child Development and Disabilities, Bengaluru, Karnataka, India*

Background:

Studies have shown that parents of children with developmental delays report poorer well-being. In most cases, parents, especially mothers, tend to ignore or deny that they are experiencing depression and suboptimal quality of life, and seldom seek help. Proper strategies implemented for dealing with caregiver stress would mean increased patience, understanding, acceptance, and overall caregiving towards their children with developmental delays, especially autism spectrum disorder (ASD).

Objectives:

In this study, we evaluated the primary care-giver depression and quality of life to assess the level of depression and the quality of life (QoL) of mothers of children with ASD that are enrolled in our center for intervention programs.

Methods:

The intervention programs in our center for young children with ASD are divided into 2 main types: Therapist-based intervention (TI) and parent-based intervention (PI). In the PI program, mothers actively participated along with the therapists and early educators in a 3 h/day program for their children with ASD at the center, followed by incorporating the same skills learnt at the center at home for at least 2 h/day. In total, we assessed 64 mothers of children with ASD at our center (47 in therapy-based, 17 in parent-based intervention programs) once before the start of the intervention program and once after at least 6-months into the intervention program. To analyze the QoL of mothers, we used the Short-form Health Survey (SF-36) questionnaire. The degree of depression was assessed by the Beck Depression Inventory (BDI) questionnaire. We compared the progress of mothers in both of our intervention programs to better understand the need for additional support programs for mothers of children with ASD. Paired t-test and Spearman correlation were used for analysis.

Results:

Before the start of intervention, 47 of 64 mothers (34/47 – TI; 13/17 - PI) showed varying degrees of depression upon evaluation including 7 cases of severe or extreme depression. At the end of 6-months after start of intervention for their children, 28 mothers (21/47 – TI; 7/17 - PI) showed signs of depression, with no cases of severe and extreme depression. After 6-months, a significantly higher number of mothers in the PI group showing improvement than those in the TI group ($P<0.05$). For QoL evaluation, 55/64 mothers showed improvement in their quality of life after 6 months. Here again, mothers in the PI group showed significant improvements in many more domains than those in the TI group ($P<0.05$). Both these results corresponded with improvements seen in their children due to the intervention programs.

Conclusions:

Based on our results, we observed that the mothers from the PI program fared better than the mothers of children in the TI program. This suggests that along with the positive feedback of the improvement seen in their children, additional weekly programs targeting the mothers in the parent-based intervention helped the mothers to cope up better.

158 **185.158** Evaluating Maternal Participation in Mobile Health Research

*J. Toroney[1], **J. K. Law**[1,2,3], R. Ellis[4], S. Dhingra[4] and P. H. Lipkin[1,2,3], (1)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (2)Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD, (3)Johns Hopkins University School of Medicine, Baltimore, MD, (4)Public Good Ventures Limited, Atlanta, GA*

Background: With the advancement of digital technology, mobile health apps facilitate the routine collection of health data, constituting an invaluable asset of information to organizations (e.g. government and private). Such data is often already collected and easily accessed, raising an interest in utilizing such data for public good; however, little is known about an individual’s willingness to share this data freely for research purposes.

Objectives: (1)Evaluate the feasibility of collecting mobile health data (mHD) for research purposes (2) Utilize mHD to inform future health-related research

Methods: The Caregiver Health and Activity Monitoring Pilot Study (CHAMPS), was a 16-week study asking mothers in the Interactive Autism Network (IAN) - a community-powered research network that focuses on improving the lives of individuals with ASD and their families - to: (1) complete multiple brief online questionnaires about their own perceived physical health and well-being and (2) share their mHD (activity level) with researchers by connecting their Fitbit to a secure online platform.

Eligible IAN mothers were emailed a study invitation to join CHAMPS. Eligibility criteria included: (1) being the mother of a child or adolescent with ASD and (2) participating in a previous questionnaire that asked mothers if they owned a Fitbit. Study invitations were sent to two groups: Group A consisted of mothers that already owned a Fitbit and Group B included mothers that did not own an activity monitor. A Fitbit was purchased for the latter group. Data was collected monthly from internet-based questionnaires consisting of custom questions and standardized surveys, including 10-item PROMIS Global Health. Participants were asked about their perceived health, well-being, and Fitbit use.

Results: A total of 109 mothers joined CHAMPS. Overall, 83% (n=91) of participants completed the study; however, these rates differed by group. Group B had a significantly higher completion rate, demonstrating greater engagement (Group A=63%, Group B=98%).

At the beginning of the study period, 22 participants in Group A connected their Fitbit. Several participants contacted our research team because they no longer possessed a working Fitbit. By contrast, 100% of Group B participants connected their Fitbit to the study platform. The inability to connect the Fitbit was related to not having a functional device rather than the platform's capability.

The final questionnaire presented participants with the opportunity to express their feelings and thoughts in an open-ended format. Group A focused on the positive aspects of contributing to research while Group B focused on their experiences using the Fitbit. The novelty of having a Fitbit, or not, seemed to influence how participants viewed their participation.

Conclusions: New Fitbit users were more engaged in CHAMPS as compared to mothers that already owned an activity monitor. The new Fitbit user group had higher study completion rates, all participants shared their Fitbit data, and feedback focused on the Fitbit itself rather than the study as a whole. Mothers of children and adolescents with ASD are willing to share mobile health data for research.

159 **185.159** Exploring Factors Related to Decision-Making and Barriers to Service for Single Parents

N. Bardikoff *and M. Spoelstra, Autism Ontario, Toronto, ON, Canada*

Background: Research on children with ASD has shown that appropriate interventions, delivered at appropriate developmental periods, can lead to marked increases in functioning across a range of domains (for review, Warren et al., 2011). Given the importance of treatment choice and timing, families' decisions about intervention type and subsequent service use, are of great interest to both the research and professional fields. Research shows that socioeconomic status, autism knowledge and education level affect treatment and service use (Pickert & Ingersoll, 2015). Yet most studies examine the experiences of multi-parent households, few have addressed the possible added considerations and barriers experienced by single parents.

A survey of caregivers of individuals with ASD in Ontario found that 33% of respondents identified as single parents, (Ontario average single-parent households, 20%; Statistics Canada, 2016). Given the high number of single-parent households within the ASD community it is important to determine needs and experiences when accessing services.

Objectives: To fill knowledge gaps of different family structures by examining how single-parent households make decisions about treatment and subsequent barriers to service they experience.

Methods: Autism Ontario conducted an online survey for caregivers in April, 2017. It was distributed across our network, via partner organizations and Ontario's regional autism providers. It was available in English and French, and focused on various aspects of service and support.

Results: There were 3,130 respondents, 1,024 who identified as single parents. The majority of respondents cared for male children (81.2%) and 15.3% indicated that they cared for more than one child with ASD. Children ranged from toddlers to adults.

Respondents rated potential barriers to service on a 5-point likert scale. After controlling for age of the child, child's gender and region, single-parents rated financial restrictions, travel, services not available at convenient times, previous poor experiences with professionals, lack of response from providers and lack of in-home services as significantly larger barriers to service compared to non-single parents ($Fs > 4.14$, $ps < 0.05$). Factors including, child deemed ineligible, long waitlists and services in non-preferred language were not significantly different between single- and non-single parent respondents ($Fs < 2.27$, $ps > 0.05$).

Respondents rated amount of influence various sources have during the decision-making process regarding treatment. After controlling for age of the child, child's gender and region, single-parents rated Ministry of Children, social media and news media as significantly more influential sources than non-single parents ($Fs > 7.55$, $ps < 0.05$). Non-single parents rated current research as a significantly more influential source than single-parents (F (1,1996) = 8.08, $p < 0.01$). Sources including, family and friends, other parents, professionals, school personnel and your own understanding of your child were not significantly different between single- and non-single parents ($Fs < 3.7$, $ps > 0.05$).

Conclusions: Single-parent households experience different barriers to service and rely on different sources of information when considering intervention options for their children. We will discuss the implications of these findings in regards to the tailoring of services and supports for children of families that differ from typical multi-parent households.

160 **185.160** Exploring the Mediating Role of Parenting Stress in the Association between Adolescent Depressive Symptoms in ASD and Disruption in the Home Environment: Does Parenting Efficacy Ameliorate Spillover?

H. K. Schiltz[1]*, A. J. McVey*[1]*, A. D. Haendel*[2]*, K. Willar*[3]*, J. Karst*[4]*, A. Carson*[5] *and A. V. Van Hecke*[6]*, (1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Children's Hospital Colorado, Aurora, CO, (4)Medical College of Wisconsin, Milwaukee, WI, (5)Baylor College of Medicine, Houston, TX, (6)Psychology, Marquette University, Milwaukee, WI*

Background: Co-morbidities are common among youth with ASD (Leyfer et al., 2006). It is unclear, however, whether co-occurring symptoms have implications for global levels of family functioning over and above autism severity alone. Previous research has identified links between child characteristics and level of parenting stress (McStay, Dissanayake, Scheeren, Koot, & Begeer, 2014). This raises the possibility that levels of co-

occurring symptoms may amplify parenting stress and, in turn, increase family disruption. Moreover, parents' efficacy and perception of parenting competence is known to play an important role in family functioning (Giallo, Wood, Jellett, & Porter, 2013), and therefore may buffer the impact of their child's difficulties on the home environment.
Objectives: To address the aforementioned possibilities, the present study explored 1) whether depressive symptoms contribute to environmental disruption in the home, controlling for ASD severity, 2) if parenting stress mediates the relation between depressive symptoms and disruption in the home, and 3) a moderated meditation model to determine whether parenting efficacy acts as a moderator of these effects.

Methods: Caregivers of 92 adolescents with ASD completed the questionnaires used in this sub-study as part of a larger RCT of the PEERS® social skills intervention; only pre-intervention data was used in the analyses. ASD was confirmed using the ADOS-G and all participants had an IQ greater than or equal to 70 on the Kaufman Brief Intelligence Test. The Confusion, Hubbub, and Order Scale (CHAOS) was used to measure global levels of disruption in the home environment, the Stress Index for Parents of Adolescents (SIPA) was used to measure parenting stress, and the Parent Sense of Competence Scale (PSOC) was used to assess parents' perception of their parenting efficacy. The Social Responsiveness Scale (SRS) was employed as a proxy of autism severity and the Short Mood and Feelings Questionnaire (SMFQ) as an index of adolescent depressive symptoms.

Results: A multiple linear regression predicting CHAOS from SRS and SMFQ was significant $F(2,89) = 5.57$, $p < 0.01$ and revealed a significant main effect of SMFQ $b = 0.36$, $p = 0.001$, controlling for SRS. A PROCESS mediation model was used to test the mediating role of SIPA and revealed a significant indirect effect $b = 0.79$, [CI: 0.45, 1.26]. Follow up conditional PROCESS analyses were employed to test the moderating role of PSOC on the previous mediation model. No significant interaction effects were identified and, thus, the mediation model does not differ at varying levels of parent efficacy.

Conclusions: Findings from this study suggest that heightened depressive symptoms are linked with increased disruption in the home environment, beyond the effect of autism severity. Moreover, this association appears to be driven by an increase in parenting stress. Lack of interaction effects suggests that parent efficacy may not buffer the impact of child depressive symptoms on environmental disruptions, although it likely operates in other ways to facilitate positive family functioning that are not captured in these analyses. Overall, both autism symptoms and mental health may be important targets for intervention and avenues to enhance family functioning.

161

185.161 Fabric to the Facts. Understanding Social Problems and Co-Occurring Conditions in Young Adults with Autism Spectrum Disorder

***L. Mattys**, KU Leuven, Leuven, Belgium*

Background:

As children with autism spectrum disorder (ASD) become adults, adaptive functioning usually improves, but social problems seem to remain or even increase, and comorbid psychiatric disorders are likely to occur. Though current research seeks better understanding of these problems, our knowledge remains theory-driven and is often not directly clinically applicable, leaving the group in need.

Objectives:

This study proposes a shift of perspective, including lived experiences from adults with ASD instead of outside perceptions from researchers, to get an insider understanding of the problem and make recommendations on how to improve current clinical practice by better targeting existing initiatives and interventions.

Methods:

Fourteen young adults with ASD (ages 17-26) were interviewed using a semi-structured interview guide that addressed topics that were previously found to be the most salient developmental themes for typically developing young adults. Their contents of these interviews were transcribed and analysed using Interpretative Phenomenological Analysis. Special precautions were taken to avoid interpretational biases by member-checking the validity of our findings with participants, and including other researchers, so that inter-rater reliability could be checked.

Results:

Participants experienced continued social problems, that had become more covert as they had learned to avoid visible social errors. Tremendous effort was reported to be put into adjusting to social rules and expectations of others and hiding symptoms of ASD. Exhaustion, inhibitory problems, difficulties imagining the future and inflexible thinking were mentioned as the biggest causes of lowered well-being. Interviewees also discussed their own methods of coping, such as creatively expressing emotions or physical exercise, highlighting potentially helpful strategies to explore that are currently not included in general guidelines for clinical practice.

Conclusions:

These findings open new directions for research to follow regarding the development of social skills of children with ASD as they grow into adults, as well as regarding clinical interventions based on self-advocacy of the targeted patient group.

162

185.162 Family Accommodation of Restricted and Repetitive Behaviors in Children with ASD

***J. Koller**[1], D. A. Zachor[2], I. Feldman[3], C. Shulman[4], E. Ben-Itzchak[5] and E. R. Lebowitz[6], (1)Seymour Fox School of Education, Hebrew University of Jerusalem, Jerusalem, Israel, (2)The Autism Center/Pediatrics, Tel Aviv University / Assaf Harofeh Medical Center, Zerifin, Israel, (3)The Hebrew University of Jerusalem, Jerusalem, Israel, (4)The School of Social Work, The Hebrew University of Jerusalem, Jerusalem, Israel, (5)Bruckner Center for Research in Autism, Communication Disorder, Ariel University, Ariel, Israel, (6)Yale Child Study Center, Yale School of Medicine, New Haven, CT*

Background: This study is the first to examine family accommodation of core ASD symptoms. Family accommodation has been defined as the ways in which parents modify their behavior to help a child avoid or alleviate states of distress and negative affect caused by emotional disorders (Lebowitz & Bloch, 2012; Lebowitz, Scharfstein & Jones, 2014). Research demonstrates that accommodation is common among families of children with OCD and anxiety disorders. Furthermore, high levels of accommodation have been repeatedly associated with greater symptom severity, lower functioning, and poorer treatment outcomes for children, and with distress in parents (Caporino et al., 2011; Lebowitz & Bloch, 2012; Lebowitz et al., 2013; Lebowitz, Scharfstein & Jones, 2014; Storch et al., 2007).
The only published study of family accommodation in children with ASD focused on accommodation of anxiety symptoms. Family accommodation

was similar to that reported by parents of anxious children without ASD, and correlated with severity of the anxiety symptoms (Storch et al., 2015). There has yet to be an examination of family accommodation of RRBs, or its associations with RRB and autism severity. Previous research has found associations between ASD symptom severity and specific parental behaviors (e.g., Gulsrud, Hellemann, Shire & Kasari, 2016; Woodman, Smith, Greenberg & Mailick, 2015), underscoring the merit of such an examination.

Objectives: To preliminarily examine family accommodation of RRBs and its relation to RRB severity in children newly diagnosed with ASD.

Methods: Participants include 19 children (6 females; mean age = 7.71, SD = 3.72) diagnosed with ASD at a tertiary autism center located at a large medical center in central Israel, and their parents. All participants underwent comprehensive assessments including medical history and neurological examination, cognitive and adaptive behavior evaluations and diagnostic measures. Measures include the Family Accommodation Scale for Restricted and Repetitive Behaviors (FAS-RRB; Koller, Shulman & Lebowitz, 2016), the Repetitive Behavior Scale-Revised (RBS-R; Bodfish, Symons, & Lewis, 1998), the Autism Diagnostic Observation Schedule 2 (ADOS2; Lord, DiLavore & Gotham, 2012), and the Autism Diagnostic Interview-Revised (ADI-R; Lord, Rutter & Le Couteur, 1994).

Results: Accommodation was prevalent, with 17 out of 19 participants (89.47%) reported engaging in accommodation at least once a month and 13 (68.42%) reported daily accommodating their child's RRBs. The most frequently reported forms of accommodation included participating in RRB-related actions (reported by 14 parents), assisting avoidance of RRB-related stimuli (14), and providing RRB-related items (13). Family accommodation was significantly positively correlated with RRB severity (r =.769, p <.001), indicating that increased accommodation was associated with more severe RRBs.

Conclusions: This preliminary study provides the first evidence that parents of children with ASD commonly accommodate their child's RRBs and that the accommodation is positively associated with the severity of the RRBs. These results indicate that accommodation of RRBs may follow a similar pattern to what has been reported in OCD and anxiety disorders (Lebowitz et al., 2014). These findings add to the understanding of autism symptomatology, point to an important and previously unexamined area of research, and highlight heretofore unexplored avenues for potential interventions.

163 **185.163** Health of Mothers of Children with Autism Spectrum Disorders and Intellectual Disability: A Case-Control Study

A. Al Ansari[1] *and H. Jahrami*[2]*, (1)Psychiatric Hospital, Manama, Bahrain, (2)Ministry of Health, Manama, Bahrain*

Background: The impact of caring for a child with a disability has been observed among mothers of children with autism spectrum disorders (ASDs) or Intellectual Disability (ID) in Western countries, but little is known about these challenges in the Arab region.
Objectives: The aim of the current study is to gather knowledge about physical health, mental health and Quality of Life (QOL) experienced by Bahraini mothers of children with ASD or ID in comparison to the mothers of healthy controls (HC).

Methods: Using a cross-sectional study design, data about mothers' demographic characteristics, general health, QOL and functioning were collected through direct interviews. The participants included 90 mothers with 30 mothers from each group (ASD, ID, HC).

Results: Mothers of children with ASD reported more psychological, and environmental problems and received more help from family members when compared to parents of ID and HC children. All groups obtained a similar score on QOL total score and physical health score. Parents of ASD and ID children scored lower than the parents of HC children on GAF measurement.

Conclusions: Mothers of children with ASD and, to a lesser extent, mothers of children with ID needed more social support and counseling regarding their own mental health after their children received a diagnosis.

164 **185.164** IMPACT of Parent Education on Families in South-EAST Europe

D. R. Preece[1]*, J. Stošić*[2]*, E. Theodorou*[3]*, J. Troshanska*[4]*, K. Mavrou*[3]*, L. Symeou*[3]*, J. Frey Škrinjar*[2] *and V. Trajkovski*[5]*, (1)Faculty of Education and Humanities, University of Northampton, Northampton , United Kingdom of Great Britain and Northern Ireland, (2)Department of Inclusive Education and Rehabilitation, University of Zagreb, Zagreb, Croatia, (3)School of Humanities, Social and Education Sciences, European University Cyprus, Nicosia, Cyprus, (4)Macedonian Scientific Society for Autism, Skopje, Macedonia, The former Yugoslav Republic of, (5)Faculty of Philosophy, University of Ss Cyril and Methodius, Skopje, Macedonia, The former Yugoslav Republic of*

Background: Autism challenges traditional parenting styles, and can make parents feel deskilled and disempowered, especially if little information or support is available to them. Providing accurate information about autism to parents, and teaching them to adapt their parenting using good autism practice has been shown to be effective in improving personal, educational and social outcomes for individuals with autism and their families (Bearss et al 2015, Farmer and Reupert 2013). However, such support is extremely limited or non-existent within some south-east European countries.
Objectives: A three-year European Union-funded project has been established involving family members, professionals and academics. Its objectives are to develop a core parent autism education curriculum and locally appropriate parent education materials and methods; to provide parent education in three diverse south-eastern European countries (Croatia, Cyprus and the Former Yugoslav Republic of Macedonia) where diagnosis and service provision are emergent; to develop local parent education teams within these countries to ensure sustainability; and to evaluate the impact of the parent education events upon families attending.

Methods: After reviewing the literature and surveying parental priorities in the three countries, a 12-hour parent education programme and locally differentiated training materials were developed. In total, five cohorts of approximately 20 parents each will receive parent education within each of the three countries. A combined process and outcome mixed methods evaluation methodology (Royse et al 2009) is being used to evaluate the project. Data are gathered via pre-attendance, post-attendance and follow-up (3-month) parent questionnaires – incorporating the CarerQoL quality of life scale (Hoefman et al 2014) – from all participants, semi-structured interviews with a purposive sample of parents, trainer focus groups and reflective diaries, and document analysis. We here report on quantitative (n = 108) and qualitative data (n = 20) from parent cohorts 1 and 2.

Results: Quantitative data identify that >90% of respondents have improved their understanding of autism, >80% report improved child communication and >75% report improvements in overall family life, their ability to predict their child's behaviour and their ability to respond to concerns and comments from the broader family. Carer QoL data indicate increased parental happiness following attendance (p=.001). Key themes from qualitative data are the positive impact of attending the parent education programme, increased awareness regarding sensory and communication issues and improvements in everyday life. Parents also reported that attendance provided opportunities to meet other parents and reduced social isolation.

Conclusions: Data from parent cohorts 1 and 2 identify that parents who have attended the parent education programme have found it beneficial, and that it has had a positive impact on their family life. Key areas of impact have been improvements in communication and improved management of sensory and behavioural issues. This supports the continued and wider provision of parent education within these countries. Further data from cohorts 3 and 4 will have been collected and analysed by the time of INSAR 2018.

165 **185.165** Investigating the Real-Word Application of Social Stories™ within Education and Home Settings

E. Smith[1], *H. Johnson*[1], *A. Constantin*[2] *and M. Brosnan*[3], *(1)University of Bath, Bath, United Kingdom, (2)University of Edinburgh, Edinburgh, United Kingdom of Great Britain and Northern Ireland, (3)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland*

Background:

Social Stories™ are highly structured and personalised social narratives, written and delivered according to a set of criteria outlined by Carol Gray. They are widely used within the autistic community and perceived by teachers and parents to be both an effective and acceptable treatment. Despite their popularity, meta analyses of the research literature reveals mixed findings regarding effectiveness. To date there has been little in the research literature to show how Social Stories™ are being developed and delivered by practitioners and parents in real-word settings and therefore it may not be possible to consider the implications for effectiveness in practice from the research literature.

Objectives:

To investigate how Social Stories™ are being used by parents and practitioners within education and home settings, and consider how this compares to their use within research studies.

Methods:

An online survey was conducted with 103 practitioners and 36 parents over a 6-month period. The survey comprised a series of self-report questions to assess common practices for Social Story™ construction and delivery. Questions related to the 11 intervention variables used in Kokina and Kern's (2010) meta-analysis to enable comparisons to be made between research and practice.

Results:

All respondent reported experience of using Social Stories™ but relatively few parents (40%) and practitioners (61.7%) had received specific training and less than half (48.5%) indicated that Gray's criteria were consistently adhered to.

Table 1 presents a comparison between the proportion of research studies relating to the different intervention variables included in Kokina and Kern's (2010) meta analysis, and the percentage of practitioners and parents who report using Social Stories™ in this way. For several features the majority of participants reported using Social Stories™ in the manor that was found to be most effective (brief intervention; using words and pictures; targeting a single behaviour; use of a functional assessment; use of comprehension checks). Other areas highlighted disparities (when the story was read; who read the story; story length). In addition, when considering the behaviours targeted for intervention both practitioners and parents reported the most common use of Social Stories™ for supporting children with transitions and novel situations, yet very few research studies have focussed on this area (supported by an updated literature search in March 2017).

Conclusions:

The current Social Stories™ research literature is largely based upon addressing inappropriate behaviours in autism and highlights a huge variation in the level of effectiveness across studies. In practice, however, Social Stories™ are largely not being written to Gray's criteria and are being used to assist in transitions and novel situations for children with autism. The effectiveness of Social Stories™ derived from the research literature may therefore have limited relevance for the effectiveness of Social Stories™ in practice. Further research is required to consider the impact of how Social Stories™ are developed and delivered in practice to minimise potential research-practice discrepancies, and to ascertain the impact of violating Gray's criteria upon Social Stories™ effectiveness for children with autism.

Funding for the project was provided by The Leverhulme Trust.

166 **185.166** Maximizing Adolescent Post-Secondary Success: Development and Refinement of a Novel Intervention for Parents of Youth with ASD

A. V. Kirby[1], *K. J. Feldman*[2], *M. Himle*[2], *M. Diener*[2], *C. Wright*[2] *and J. Hoffman*[2], *(1)University of Utah College of Health, Salt Lake City, UT, (2)University of Utah, Salt Lake City, UT*

Background: Adolescence is a critical time during which families of adolescents with autism spectrum disorder (ASD) plan and prepare for the future. Recent evidence suggests that parents' expectations during adolescence act as significant mediators of key outcomes for adults with ASD (Kirby, 2016). Studies have also found that higher expectations for the future and higher parental self-efficacy are associated with more family engagement in positive post-secondary preparation activities (e.g., social activities, volunteer work/employment, parent-youth discussions about the future, working toward goals; Holmes et al., under review).

Objectives: To develop and refine a novel intervention to provide support for parents of youth with ASD, focused on increasing positive post-secondary preparation activities by addressing parents' expectations and self-efficacy related to preparing youth for adulthood.

Methods: As part of the intervention development process, we followed 15 parent-youth dyads (youth with ASD and without intellectual disability) over nine months to understand day-to-day concerns and approaches to preparing for adulthood. Informed by that preliminary work, published empirical findings, and psychological theories (i.e., self-efficacy theory, expectancy-value theory), we developed a five-week group intervention: Maximizing Adolescent Post-Secondary Success (MAPSS). An interdisciplinary research team collaborated throughout the MAPSS intervention development process. We then recruited families to participate in a first iteration of the program (n=4 mothers of youth with ASD and their sons, ages 14-16). Sessions were 90 minutes per week for five weeks and included a concurrent life skills group for the youth with occasional interaction with parents (e.g., during weekly goal setting). Parent participants were required to be a primary caregiver of an adolescent (ages 14-18 years) with

ASD in high school and anticipating receipt of a high school diploma. Upon completion, we collected participant feedback about the program. The primary outcome measure was the Transition Preparation Activities Measure (T-PAM; Kirby, n.d.), secondary measures included the Competency factor of the Family Empowerment Scale (Koren et al., 1992) and Adulthood Expectations Questionnaire (AEQ; Kirby, n.d.), all of which were administered at baseline and at program completion.

Results: Seventy-five percent of participants remained in the program (n=1 dropped out due to a family emergency, but completed an exit interview to provide feedback). Table 1 contains summary participant feedback about the program. Pre- and post-study T-PAM results supported the primary hypothesis. After the five-week program, overall preparation rating increased 13%, overall worry for the future rating decreased 12%, and endorsement of preparation activities increased 7%. No notable changes were identified on the secondary measures.

Conclusions: Results of the first iteration of the MAPSS group suggest it was well-received by participants and provided appropriate content. We did see modest improvements in primary outcome measures but not in secondary measures; the team is reviewing appropriateness of secondary measures as well as adjustments to the content to more effectively target those outcomes. Participant suggestions for improvement included expanding the content focused on adolescent motivation and incorporating more parent-youth combined activities, which will be explored prior to further pilot testing. Future research will include measuring long-term outcomes (i.e., post-secondary outcomes).

167 **185.167** The Lived Experience of Fathers and Mothers of Children with ASD: Facilitators and Barriers to Access of Support.

M. Seymour[1,2]*, S. Allen*[1]*, R. Giallo*[2] *and C. E. Wood*[1]*, (1)Swinburne University of Technology, Melbourne, Australia, (2)Healthy Mothers Healthy Families Research Group, Murdoch Childrens Research Institute, Parkville, Australia*

Background:

Enhancing the wellbeing of parents/carers of children with a disability is recognised as an important area for disability policy and clinical practice [1]. Parenting a child with an Autism Spectrum Disorder (ASD) is associated with social isolation, increased stress, anxiety, and depression [2], along with poorer quality of life and physical health [3]. Many parents of children with ASD report substantial unmet needs (e.g., difficulty accessing services, financial pressure) [4, 5] where more directed parent mental health support is needed. Enhancing the mental health of parents in general, has flow on effects to the wider family, including promoting the potential for positive outcomes for their child [6, 7].

Objectives:

To explore the phenomenological mental health experiences of fathers and mothers of school-aged children with an ASD. Additionally, to investigate facilitators and barriers parents of children with ASD face to accessing support for their own mental health.

Methods:

Participants were four fathers and seven mothers of children (aged 8-10 years) with an ASD, living in urban Victoria, Australia. An Interpretative Phenomenological Approach (IPA) was used as it allows for the detailed examination of participants' lived experiences. Semi-structured interviews were conducted in participants' homes, work-places, or a local psychology clinic. Interviews lasted approximately 90 minutes, and were completed by two researchers who undertook flexible dialogues, while following an interview schedule. All interviews were audio recorded and transcribed verbatim. Themes capturing the participants' lived mental health experiences were consolidated into superordinate themes. A bio-ecological approach was used to guide the identification of potential facilitators and barriers to parents accessing the support they required.

Results:

Mothers and fathers reported both positive and negative impacts of parenting a child with ASD on their mental health, including worry, somatisation, exhaustion, acceptance and hope. Individual, interpersonal, and community factors were identified as barriers and facilitators to parents accessing the support they required. Within the individual domain, the importance of self-care and flexibility/restriction were identified as impacting parents' access to support for their own mental health. External perceptions and informal social support were identified as important factors within the interpersonal domain. Finally, at the community level, system understanding, access to services, financial pressure, and professional support impacted parents' access to support for their own mental health.

Conclusions:

The results of this qualitative study shed important light on the lived mental health experiences of fathers and mothers raising children with an ASD, along with their unique support needs. While fathers and mothers identified that there are many challenges to parenting a child with ASD that adversely impact their own mental health, there are also many moments of growth, acceptance and optimism. Parents identified important individual, interpersonal and community factors which impact their access to support for their mental health, many of which are modifiable. Continued research and support is needed in order to improve service capacity to provide quality care to the unique needs of mothers and fathers raising children with ASD.

168 **185.168** Open Feasibility Study: Navigator ACT for Parents to Children of Autism Spectrum Disorders (ASD) and/or Other Disabilities

T. Holmberg Bergman[1]*, B. Berg*[2] *and T. Hirvikoski*[3]*, (1)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Stockholm, Sweden, (2)Stockholm County Council Habilitation and Health, Stockholm, Sweden, (3)Habilitation & Health, Stockholm County Council, Stockholm, Sweden*

Background:

Parents of children with disabilities, especially Autism Spectrum Disorders, report psychological distress, e.g., depression, anxiety and parenting stress (e.g., Mak & Kwok, 2010, Hayes & Watson, 2013). While psychological problems of these parents have gained attention, a little is done to investigate the usefulness and affectiveness of the treatments available. However, Acceptance- and Commitment Therapy (ACT) have shown promising results in a few open pilot studies (e.g. Blackledge & Hayes, 2006; Kowalskovski, 2012). At Habilitation & Health (disability service clinics in Stockholm, Sweden), ACT has been used since 2007 as part of parent support services. During the recent years, a manual-based ACT group intervention *"Navigator ACT"* was developed to enhance psychological well-being of these parents.

Objectives:

An open study was conducted to evaluate the feasibility, parent satisfaction and preliminary efficacy of the 5-session *"Navigator ACT"* for parents to children with ASD and/or other disabilities. The following research questions were considered: 1. Is the Navigator ACT a feasible treatment method in an out-patient clinical disability services context? 2. Are parents satisfied with the intervention? 3. Is the Navigator ACT (preliminary) an effective method in increasing parental psychological/behavioral flexibility and mindfulness skills as well in reducing symptoms of depression, anxiety and parenting stress. Furthermore, a possible effect on behavioral problems of the child with disability was investigated.

Methods:

The open feasibility study was conducted at 7 outpatient disability service clinics in Sweden. A total of 94 parents were allocated to treatment. The feasibility criteria was defined as 75 % of the parents participating in at least 4/5 sessions. Parent satisfaction was measured by session- and treatment evaluations as well as evaluation of treatment credibility. For preliminary efficacy measures, pre, post and 3-month follow-up was conducted by using several self-rating questionnaires concerning e.g., symptoms of depression and anxiety, parenting stress and behavioral flexibility.

Results: 80 % of the parents attended at least 4/5 sessions. Treatment satisfaction was good and stable over the five sessions. The preliminary efficacy measures showed statistically significant increases in psychological/behavioral flexibility and mindfulness as well as reductions in symptoms of depression and anxiety.

Conclusions:

The Navigator ACT was a feasible intervention in a clinical disability service context. Navigator ACT shows promising preliminary efficacy regarding psychological flexibility and well-being of parents to children with ASD and/or other disabilities. We are currently preparing for a pragmatic multi-center randomized controlled trial concerning Navigator ACT.

169 **185.169** Parent Perspectives and Perceptions of Autism Spectrum Disorder Diagnosis: A Scoping Review and Framework Development

A. Makino[1], *L. Hartman*[2], *G. King*[2], *P. Y. Wong*[3] *and M. Penner*[1], *(1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Health Sciences Library, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Background: The growing number of children diagnosed with autism spectrum disorder (ASD) has greatly increased the demand for diagnostic assessments, leading to lengthy wait times. This is relevant as diagnosis is often needed to access behaviorally-based intervention which has been shown to significantly improve outcomes. Across the globe, there is no standard path or process for ASD diagnosis leading to a growing interest in examining the practices and quality of diagnostic assessments. Families of children with ASD are key stakeholders in the diagnostic process and their perspectives deserve to be explored and addressed.

Objectives: 1) To identify the quantity, methodological characteristics, key themes, and gaps in the current literature examining parents' and caregivers' perspectives of ASD diagnosis; 2) To create a framework for understanding parent and caregiver experiences of ASD diagnosis based on existing literature.

Methods: A scoping review was completed following Arksey and O'Malley's (2005) framework. Five databases were systematically searched (CINAHL, Embase, Medline, PsycInfo, Scopus) for the period Jan 1994–Sep 2017. Titles and abstracts were screened for relevance. 121 articles underwent full text review.

Results: Seventy-one articles met inclusion criteria. Articles consisted of quantitative questionnaire-based studies, qualitative interviews/focus groups, mixed-method designs, and reviews. The number of annual publications increased over time. Results indicate that diagnosis is a uniquely stressful and emotionally intense time for parents and caregivers. The path to diagnosis was often seen as convoluted and fraught with delays. Factors found to impact the diagnostic experience for families included clinicians' approaches to delivery of and the information and resources provided at the time of diagnosis. Based on these findings a framework was created indicating four central components of the family's diagnostic experience: 1) the journey to assessment, 2) the assessment process, 3) delivery of the diagnosis and feedback session, and 4) provision of information, resources and support. With the exception of the negative impact of wait times, perceptions of the diagnostic process itself, such as background of the assessor, methods of assessment, and setting of diagnosis, have not been thoroughly examined in the literature to date.

Conclusions: The literature demonstrates a growing interest in parent and caregiver perspectives of ASD diagnosis. The path to diagnostic assessment was long and complex for many families and should be targeted as an area for improvement. Clinicians should strive for an honest but hopeful tone with the strengths-based approach to diagnosis that families desire. The feedback session after diagnostic assessment should emphasize information and resource support as this has been identified as the most important element of the diagnostic process for families.

170 **185.170** Parental Psychological Distress and Health-Related Quality of Life: The Impact of Autism Spectrum Disorder and Parental Counseling

A. Karaivazoglou[1], *E. Papadaki*[1], *K. Assimakopoulos*[2], *G. Iconomou*[2], *G. Touliatos*[1] *and S. Kotsopoulos*[1], *(1)Day Centre for Children with Developmental Disorders, Messolonghi, Greece, (2)Department of Psychiatry, University of Patras, Rio, Patras, Greece*

Background: Parenting children with Autism Spectrum Disorder (ASD) constitutes a challenging task which puts extreme demands on families' financial, social, cognitive and emotional resources. In this respect, parents of ASD children frequently suffer from somatic and psychological complaints and report low levels of health-related quality of life (HRQOL).

Objectives: The primary aim of the current study was to measure anxiety and depressive symptoms and health-related quality of life (HRQOL) in parents of children diagnosed with ASD and determine their demographic correlates. A secondary aim was to evaluate the impact of systematic counseling on parental psychosocial functioning.

Methods: The Hospital Anxiety and Depression Scale (HADS) and the Short Form-36 Health Survey (SF-36) were used to assess anxiety, depression and HRQOL, respectively. All participants were administered these questionnaires at baseline. Moreover, a sub-group of parents were re-evaluated after 6-12 months of systematic counseling.

Results: 81 parents participated to the study, 54 with a child diagnosed with ASD according to DSM-V criteria and standardized evaluations(CARS, SCQ, ADOS-2) and 27 with mentally and physically healthy children. Parents of ASD children reported increased levels of anxiety (p=0.040) and depression (p=0.001) and lower scores in social functioning (p=0.004) compared to parents of healthy children. Among parents of ASD children, parents with younger children reported lower anxiety scores (r=0.359, p=0.010) and higher vitality (r=-0.389, p=0.006), social functioning (r=-0.389, p=0.006) and mental health (r=-0.484, p=0.000) scores. In addition, employed parents scored significantly lower (p=0.017) in the general health sub-domain of HRQOL. Twenty-three (23) parents of ASD children were prospectively followed-up and re-administered the above questionnaires after 6-12 months. Seventeen (17) of these parents had received regular parental counseling sessions, while 6 parents had not. Parents which had received counseling reported significant improvement in the mental health sub-domain of the SF36 (p=0.027) compared to parents which were not engaged in parental counseling.

Conclusions: Parenting ASD children is associated with significant psychological distress and disturbed social functioning. Systematic parental counseling may lessen parents' psychosocial burden by improving mental health-related HRQOL.

171

185.171 Parental Stress, Marital Satisfaction and Stigma in Lithuanian Parents Raising Child with ASD

R. Buivydaite[1], *C. Newton*[2] *and A. Prasauskiene*[3], *(1)University of Oxford, Oxford, United Kingdom of Great Britain and Northern Ireland, (2)Kenya Medical Research Institute, Kilifi, KENYA, (3)Psychiatry, Lithuanian Health University, Kaunas, Lithuania*

Background: The research has revealed that there are few studies about autism conducted in Eastern Europe (Mikulenaitė & Ūllevičiūtė, 2004; Lesinskienė *et al*, 2008). The research project is motivated by lack of studies on autism in Lithuania, particularly the stress experienced by the parents. Experiences of stigma leads to increased parental stress. High levels of parental stress are correlated with mental health problems like depression and anxiety (Jones *et al*, 2008).

Objectives: Therefore, we conducted a study to explore parental mental health, marital satisfaction and experiences of stigma for parents raising children with autism, cerebral palsy and controls in Lithuania.

Methods: *Participants* - parents of children with autism spectrum disorder (ASD) 137, cerebral palsy (CP) 100, typically developing (TD) 140. *Tools* - Socio-demographic questionnaire, Parental Stress Index by Abidin 1992 (PSI –SF), Couple satisfaction index by Funk & Rogge 2008 (CSI) and Family Interview Schedule stigma scale by World Health organization 1994 (FISSS). *Procedure* - parents are informed through hospital staff in Lithuania, parents association of autism and cerebral palsy. Typically developing children parents were approached via schools.

Results: Results revealed that parental stress is highly experienced in ASD and CP group. There were no parental difference between mothers and fathers of children with ASD. Also the levels of experienced stigma was equally high between ASD and CP parents', stating that in Lithuania there is no difference in experience of stigma between 'visible' and 'invisible' disabilities, contradicting the existing findings from previous studies. Moreover, this study revealed, the higher divorce rate for autism group compared with other two groups. We also found, that autism characteristics, such as difficult behaviour, lack of communication and parenting styles were the underlying factors for the parental stress among the parents of children with ASD.

Conclusions: This study revealed the underlying issues that parent's, who are raising child with autism, face in their day to day lives while raising a child in Lithuania. This research informs about the stress levels, experience of stigma and marital satisfaction that must be address with urgent support for families.

172

185.172 Parenting Adolescent Boys with Autism Spectrum Disorder (ASD) Versus Adolescent Boys with Disruptive Behaviour Disorder and Typically Developing Boys

E. O'Nions[1,2,3], *R. Roberts*[2], *E. Viding*[2] *and I. Noens*[4,5], *(1)Social, Genetic & Developmental Psychiatry, King's College London, London, United Kingdom, (2)Department of Clinical, Educational and Health Psychology, University College London, London, United Kingdom, (3)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (4)Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium, (5)Leuven Autism Research (LAuRes), KU Leuven, Leuven, Belgium*

Background:

Extant research suggests that parents of boys with disruptive behaviour adopt less adaptive parenting practices compared to parents of typically developing boys, which can constitute risk/maintaining factors in the development of problem behaviour. Disruptive behaviours are also common in children with ASD. However, no research has directly compared parenting between these groups, or explored differential relationships between parenting and disruptive behaviour severity.

Objectives:

We aimed to explore differential parenting between parents of boys with ASD, parents of boys with disruptive behaviour (DB) and parents of typically developing (TD) boys. Given that differential mechanisms are believed to promote disruptive behaviours, we hypothesised that parents of boys with ASD would resemble parents of TD boys in positive (involvement, positive parenting, supervision and monitoring), and negative (consistent discipline, physical punishment) parenting behaviours.

Methods:

Parents of boys aged 11 - 16 with DB (N = 26) and matched TD boys (N = 29) completed measures as part of a larger study. Inclusion in the DB group required (1) significant conduct disorder symptoms based on parent/teacher report, and (2) attendance of a specialist educational setting. Data from parents of boys with ASD (N = 29) were drawn from a separate study. Both ASD and DB groups spanned a range of conduct disorder symptoms (ASD mean: 4.21, SD: 4.68; DB mean: 7.63, SD: 4.13). Data on parenting were collected using the Alabama Parenting Questionnaire (Frick, 1991).

Results:

No group differences were found for parental involvement and positive parenting ($F(2,81) = .183$, p >.3; $F(2,81) = .744$, p>.3, age included as a covariate). Robust group differences were reported for supervision and monitoring ($F(2,81) = 22.81$, p<.001). Post hoc-analysis indicated that parents of adolescent boys with ASD engaged in most supervision and monitoring (significantly more than parents of TD boys), and parents of boys with DB engaged in least (significantly less than TD boys). Group differences for inconsistent discipline and physical punishment reached nominal significance, but would not survive correction ($F(2,81) = 3.715$, p=.029; $F(2,81) = 4.055$, p =.021). Post-hoc analysis indicated that parents of boys with ASD reported less inconsistent discipline and physical punishment compared to parents of DB boys. Continuous analysis within groups indicated that the severity of conduct disorder symptoms was not related to parenting in ASD and TD boys. However, in boys with DB, there was a robust relationship between (lack of) monitoring and supervision and conduct disorder symptoms (partial correlation controlling for age: $r = .702$, p<.001).

Conclusions:

We demonstrate differences in parenting behaviours between parents of TD boys, boys with ASD and boys with DB; and differential relationships between parenting and conduct disorder symptoms. Parents of boys with ASD engaged in more monitoring and supervision compared to TD parents, yet conduct disorder symptoms were significantly elevated. This suggests that a lack of monitoring and supervision is not a risk factor for conduct disorder symptoms in ASD. Longitudinal research using multiple informants is needed to explore the directionality of effects and overcome possible rater bias.

173 **185.173** Parenting Plus: Raising Children and Adolescents with Autism Spectrum Disorder

L. van Esch[1,2]*, H. Boonen*[1,2]*, G. Lambrechts*[1,2,3]*, J. Maljaars*[1,2,3]*, E. Ceulemans*[4]*, K. Van Leeuwen*[1] *and I. Noens*[2,5]*, (1)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (2)Leuven Autism Research (LAuRes), KU Leuven, Leuven, Belgium, (3)Child Psychiatry, UPC-KU Leuven, Leuven, Belgium, (4)Quantitative Psychology and Individual Differences, KU Leuven, Leuven, Belgium, (5)Parenting and Special Education Research Unit, University of Leuven, Leuven, Belgium*

Background: Parents of children with ASD face specific challenges in raising their child. Research clearly indicated that parents of children with ASD across all ages experience more parenting stress than those of typically developing children or children with other disabilities. Nevertheless, research investigating the behavioural aspects of parenting children with ASD is rather scarce.

Objectives: We aim to present the overall results of multiple studies on parenting behaviours among mothers of children with ASD. The main objectives were twofold: (1) to compare parenting behaviours among mothers of children with and without ASD, and (2) to examine whether and how mother's parenting behaviours are related to child (gender, age, IQ, ASD characteristics and behaviour problems) and mother (parental stress and psychological well-being) characteristics.

Methods: A multi-method approach was used, combining information from questionnaires, interviews, tests and observations, collected from mother-child dyads across different age groups (Preschool: 22 with and 50 without ASD; Primary school: 30 with and 39 without ASD; Secondary school: 44 with and 38 without ASD).

Results: Parenting behaviours in the ASD group were largely comparable to those in the control group; few differences were found. Across all age groups, mothers of children with ASD scored lower on observed provision of structure. In addition, mothers of preschool and school-aged children scored lower on observed sensitivity and mothers of preschool children with ASD higher on observed negativity towards their child. On the contrary, mothers of children with ASD in secondary school showed more sensitivity and creativity than mothers in the control group. Regarding self-reported parenting behaviours, mothers of preschool children with ASD stimulated the development of their child less, whereas mothers of children with ASD in the older age groups adapted the environment for their child more. However, when controlling for parenting stress, most of the group differences did not remain significant. Based on questionnaires filled out by 73 mothers of children aged 6-16 years, parental control appeared related to lower IQ scores, more ASD characteristics and less externalising behaviour problems of the child in the control group. In the ASD group, parental control was only related to the age of the child. When controlling for parenting stress, the correlation between parental warmth and externalising behaviour became significant, suggesting a suppression effect of parenting stress on this relation.

Conclusions: The findings suggest that (1) parenting behaviours are largely comparable across control and ASD group, (2) behavioural differences between both groups are mostly explained by differences in parenting stress, and (3) mothers of children with ASD become more sensitive/creative across age groups in comparison to the control group. Little child and mother characteristics are found to be related to parenting behaviour in the ASD group as opposed to the control group. Taken together, this suggests that mothers of children with ASD get increasingly adapted to the needs of their child with ASD. Parenting stress seems to have an important effect, suggesting that counsellors should not only focus on the behavioural aspects, but also take parenting stress into account.

174 **185.174** Positive and Negative Cognitive Appraisal of the Impact of Children with Autism Spectrum Disorder on the Family: A South African Study

L. Schlebusch[1,2] *and S. Dada*[3]*, (1)Division of Child and Adolescent Psychiatry, University of Cape Town, Rondebosch, South Africa, (2)Centre of Excellence in Human Development, Johannesburg, South Africa, (3)Centre for Augmentative and Alternative Communication, University of Pretoria, Pretoria, South Africa*

Background:

There is a large body of evidence that confirms that children with autism spectrum disorder (ASD) pose a range of distinct challenges to families, that parents and siblings experience high levels of stress, and that life is hard for these families. However, there is a risk that the dominant portrayal of a negative impact elicits an elaborate representation of the challenges associated with ASD, without considering any positives. Although researchers are yet to understand the full range of families' experiences when raising a child with ASD, stress and coping theory and research have shown that families can perceive (or cognitively appraise) the impact of their child with a disability as both negative *and* positive.

Objectives:

We investigated the measurement of positive and negative cognitive appraisal in the context of childhood disability in a middle-income country, and describe how South African families positively and negatively appraise the impact on the family of raising a child with ASD.

Methods:

We used the responses of 180 parents who completed the *Family Impact of Childhood Disability Scale*, which was part of the survey data gathered in a larger study that examined the perspectives of families of young children with ASD in South Africa. Participating families were recruited from 35 disability-related service providers in the Gauteng province. We assessed the reliability of the *Family Impact of Childhood Disability Scale* by calculating Cronbach's alpha and the validity by using confirmatory factor analysis techniques. We conducted statistical analyses to determine the descriptive statistics.

Results:

Our findings indicate that the measurement of cognitive appraisal of the impact of ASD on the family was measured in a reliable and valid manner, thus contributing evidence to the universal properties of positive *and* negative appraisal when raising a child with a disability. Families rated the positive appraisals to have a more substantial impact on the family than the negative appraisals.

Conclusions:

The findings of our study provide a cross-cultural perspective of the positive and negative cognitive appraisal of families who are raising a young child with ASD. Similar to other families in other countries, the participating families perceived the impact of a child with ASD as both positive *and* negative and revealed that parents are able to re-create positive meanings about their child with ASD. The positive findings portray the complexity of families and challenge the limitations and stigmatisation that society ascribes to raising a child with ASD. The research and clinical implications of these findings will be discussed.

175 **185.175** Predictors of Positive Contributions When Raising an Individual with ASD: An Actor-Partner Interdependence Model.

C. Garcia Lopez[1,2]*, P. Pozo*[2,3]*, P. Recio*[2,3] *and E. Sarria*[2,3]*, (1)UTAE, Hospital San Joan de Deu, Barcelona, Spain, (2)IMIENS (Instituto Mixto de Investigación-Escuela Nacional de Sanidad), Madrid, Spain, (3)Faculty of Psychology, UNED, Madrid, Spain*

Background: Autism Spectrum Disorder (ASD) is considered one of the developmental disorders with greatest impact on the family system. Theoretical and empirical research has typically focused on its negative impact on parental mental health, paying little attention to parents' positive perceptions regarding ASD and the positive influence that it could produce on family adaptation. A further issue concerns the fact that the majority of studies on the ASD family field consider only one of the parent's perceptions (generally mothers), not taking into account that family members affect one another. Particularly, couples affect each other cognitively, emotionally and behaviorally, which implies the need to consider a systematic perspective when studying ASD family adaptation. Taking into account the limitations identified in previous research, we explore the notion that parental positive perceptions might be influenced by the child with ASD but also by the psychological adaptation of the partner.

Objectives: The goal of this study is to test the benefits and potential use of the actor-partner interdependence model (APIM) in examining how different psychological adaptation measures of fathers and mothers of children with ASD influence each other's perception of positive contributions regarding their child with ASD.

Methods: 135 Spanish father-mother dyads raising individuals with ASD completed validated questionnaires measuring different psychological adaptation measures, *i.e*., stress, anxiety, depression, sense of coherence and positive contributions *i.e., happiness and fulfillment, personal growth and maturity* and *strength and family closeness.* We first fitted a series of single predictor models to test for possibly confounding variables, *i.e.,* parent and child age, family income, education level, ASD severity and behavior problems, and included the ones significantly associated with outcome measures in the final APIM models. Three sets of four models, *i.e*., one for each positive contribution outcome, were specified using a multilevel modeling (MLM) approach.

Results: Multilevel analysis revealed some actor effects of sense of coherence, stress and anxiety, and some partner effects of anxiety and depression to be important determinants of the perception of positive contributions, above and beyond child and sociodemographic factors. ASD severity, child age and family income were also identified as significant predictors of both progenitors' perceptions of positive contributions.

Conclusions: The psychological adaptation measures here explored have proved to be relevant determinants of both progenitors' perceptions of positive contributions regarding ASD, and should therefore be screened by clinicians, when working with ASD families. Professionals should also consider adjusting expectations according to the child's ASD severity given its negative relationship with the perception of positive contributions. Finally, governments should consider new policies aiming to support ASD families' treatment expenses.

176 **185.176** Public Places and Social Participation : Obstacles Faced By Parents with ASD Children

F. Beauregard[1]*, M. Couture*[2] *and C. Gauthier-Boudreault*[1]*, (1)Université de Sherbrooke, Sherbrooke, QC, Canada, (2)Rehabilitation, Universite de Sherbrooke, Sherbrooke, QC, Canada*

Background: There has been little research into the experiences of children and families (Hanvey, 2003) when frequenting public spaces. According to the Participation and Activity Limitation Survey, social participation tends to diminish with the severity of the child's disability or when parents lack support (Statistics Canada, 2006). Another factor that could also influence social participation is the nature of the child's disorder. In fact, the existence of an invisible disability such as autism spectrum disorder (ASD) could impede families' use of public spaces. According to the most recent studies, the prevalence of persons with ASD was 11.3/1000 (1 in 88) in 2008. Problem behaviours are also frequent (APA, 2013; Poppes et al., 2010). For families of children with an ASD, their problems with communication and social interactions can make it difficult to be in public spaces. Sallafranque et al. (2012) have identified numerous obstacles to social participation for children with an ASD. However, obstacles to participation have not been examined from the standpoint of presence in public spaces. Moreover, few studies have looked at the repercussions of these disorders in terms of social participation in the community. Thus, the aim of this study was to develop a profile of these families' experiences with public spaces and to document the obstacles to their participation.

Objectives: In this communication, we present the obstacles faced by parents when they frequent public places with their ASD child.

Methods: This was a descriptive survey. Parents were recruited through parents' associations (Quebec Autism Federation) and invited to complete an online questionnaire that took approximately 30 minutes. The questionnaire was intended for parents of children (0-21 years) with an ASD. The online questionnaire was developed based on a literature survey and the International Classification of Functioning, Disability and Health (ICF). It consisted of both closed and open-ended questions that documented the public spaces into which the families went and the obstacles to their social participation. One open question was about the obstacles that parents encounter when frequenting public places with their ASD child.

Results: About 100 parents completed the online questionnaire. The results of the questionnaire suggest that these parents visit very few public spaces. Those they visit are primarily utilitarian in nature, such as grocery stores and malls. This study showed that going into public spaces is stressful for these parents because of several obstacles. These were grouped into three categories: 1) sensory stimuli, such as sounds, lights, and crowds 2) attitudes and perceptions of other people, whether suppliers or users of services; 3) concerns for their children's safety. The analysis also revealed that the obstacles could influence each other.

Conclusions: A better understanding of these families' situation could become a point of reference in developing services. This could make it easier to ensure that a proposed adaptation actually meets the needs of this population and that efforts to sensitize the people involved or others who use these spaces are targeting the right issues.

177 **185.177** Reimagining Autism: Drama, Theatre, Autism and the Illuminating Blind Spots of Interdisciplinary Collaboration

ABSTRACT WITHDRAWN

Background:
Spectrum Conditions' was an interdisciplinary collaboration between drama and psychology at the University of Kent (2011-14), funded by the Arts and Humanities Research Council (AHRC). As communication, social interaction and social imagination are core characteristics of theatre as well as being diagnostic features of autism spectrum disorders, theatre methods are attracting increasing interest in the field as interventions with the potential to help children with autism connect to the social world (Corbett, 2016, Lerner et. al. 2016).

The project assessed the feasibility and justification for further research of this novel school-based theatre intervention. Participatory performance techniques (emerging from the field of applied theatre) extend the skills-based approaches of role-play and social scripts to engage children through improvisation and intensive interaction. The approach involved small groups (3-4) of autistic participants (22 children aged 7-12) with varying levels of ASD interacting with practitioners in themed multisensory scenic environments.

A theme of this paper is the lessons to be learned from the inter spaces of collaboration between disciplines: questions of what constitutes evidence, the exposure of methodological "blind spots" and the ways in which the practice has subsequently cast new light on imagination and gender

Objectives:

1.To establish the feasibility of the intervention and whether it produces measurable effects;

2.To develop a template for the creative laboratory, including programmes of training for practice-based autism research.

3. To evaluate the efficacy of drama as a research tool for autism

Methods:

The original research involved a series of immersive installations, contained within the 'pod', a portable structure (functioning like an interactive multi-sensory room). The environments were designed to facilitate communication, social interaction, imagination and imaginative play. Participants (22 children with varying levels of ASD, aged 7-12) encountered a range of stimuli, triggers and responsive technologies.

Before and after the intervention, study participants completed measures of social interaction, communication, emotion recognition, and parents and teachers questionnaires before and up to twelve months after the intervention. Feasibility was evaluated through process (recruitment, retention, blinding, inter-rater reliability, willingness of children to engage), resources (space, logistics), management (dealing with unexpected changes, ease of assessment), and scientific data (statistical analyses).

Results:

Children, parents and teachers reported high satisfaction with the intervention; missing data was relatively low; key assessments were implemented as planned; evidence of potential effect was demonstrated on several key outcome measures. Some reported difficulties were encountered with recruitment, test administration, parental response, and setting up the pod.

Conclusions:

Imagining Autism may be a feasible approach particularly for special education schools. Strengths include the novelty of the approach, implementation in the real world; education settings, focus on sensory processing and imagination. However, it was the unexpected insights emerging from the project that are the focus of this paper and that are consistent with new developments in autism research: specifically, recognition of social creativity in autism and what the practice revealed about female presentations of autism.

178 **185.178** Shifting Sands: Examining Social Support Needs of Children with ASD and Their Families across the Pathway of Development

D. B. Nicholas[1] *and L. Lach*[2,3]*, (1)University of Calgary, Edmonton, AB, Canada, (2)School of Social Work, McGill University, Montreal, QC, Canada, (3)Departments of Pediatrics and Neurology/Neurosurgery, Faculty of Medicine, McGill University, Montreal, QC, Canada*

Background: Social support is a social determinant of health that plays an important role in the well-being of parents as they care for their child(ren) with ASD. Social support includes formal resources (e.g., government funds) and informal help and engagement (e.g., family, friends). While it is intuitively recognized that social support needs shift with advancing age and changing circumstances across the life course, the nature and extent of needs for support over time and circumstance are unclear. Currently, little is known about the support needs of parents as they move through their child's developmental transitions (e.g., diagnosis, school entry, transfer to high school, exit from high school, etc.).
Objectives: This qualitative study examined the following question: What types of support do parents of children with ASD need at varying points of child and family development (at diagnosis, entering primary school, entering high school, and exiting high school)?

Methods: Utilizing an interpretive description approach (within a larger study), group interviews were conducted with n=50 parents of children with a neurodevelopmental disability. In this presentation, we will focus only on parents of children with ASD. Data addresses participant experiences and identifies parental needs for social support and services over time.

Results: Findings offer support experiences and needs over time. Overall, accessed social support was commonly insufficient relative to support needs. Parents reported they required, by default, to independently seek needed supports and services. They described ongoing needs for navigational support and peer connection with other parents. At diagnosis, parents reportedly required information about ASD, service guidance and targeted navigational support; they sought external support that offered messages of hope for the future as they adjusted to the diagnosis of ASD. Once the child had reached a more stable point relative to resource access, parents needed ongoing support in their continuing adjustment and, in some cases, relationship stability amidst the challenges and 'new norm' of ASD. Upon school entry, support in managing changing relationships within the school system emerged. Stigma was increasingly noted over time as the child's expression of ASD more visibly rendered differences from neurotypical peers. Upon high school entry, families expressed challenges due to fewer resources; they worried more about safety in unsupervised settings such as in school buses, and amidst potential (and actual) peer bullying toward their adolescent. Concerns about transition to adulthood more strongly emerged later in (and beyond) high school.

Despite nuanced differences and shifts across development, existing services were reported as common in terms of being insufficient. There was a reported lack of available knowledge about existing services and service needs at particular developmental stages.

Conclusions: These findings inform overall support planning as well as identify areas to refine along the developmental pathway, as per individual and family needs. Support needs emerge as continuing yet shifting, with increased focus warranted on anticipated needs, goal setting, and activity/targeted outcome planning. Recommendations for support delivery will be offered in the presentation, as will implications for program and policy development.

179

185.179 Sibling Relationships in Families of Children with ASD

Y. Rum[1]*, D. A. Zachor*[2]*, Y. Armony*[1] *and E. Dromi*[3]*, (1)Tel Aviv University, Tel Aviv, Israel, (2)The Autism Center/Pediatrics, Tel Aviv University / Assaf Harofeh Medical Center, Zerifin, Israel, (3)Constantiner School of Education, Tel Aviv University, Tel Aviv, Israel*

Background:

Sibling relationships include warm qualities such as affection, companionship, and intimacy, and consist also of conflict, rivalry and power. These relationships are often the longest and most important bonds a person has throughout life (Boer, Dunn, & Dunn, 2013; Gass, Jenkins, & Dunn, 2007). The influential role that Typically Developed (TD) siblings of children with Autistic Spectrum Disorder (ASD) play on their brother or sister's social and cognitive development was recognized in previous research (Ben-Itzchak & Zachor, 2016). However, little is known about siblings' relationships in families of children with ASD.

Younger siblings of children with ASD have been studied mainly in the context of looking at early signs of ASD in high-risk populations. Few studies have focused on older TD-siblings and on the siblings' relationships (Kaminsky & Dewey, 2001; Rivers & Stoneman, 2003). The limited number of studies on this topic requires additional data, which should be collected in different cultures with diverse methodologies.

Objectives:

- To explore the perspective of the older TD-sibling on his/her relationship with his/her younger sibling with ASD.
- To compare questionnaire results with open-ended answers given during interviews.

Methods:

Twenty-five sibling dyads (10 same-gender, 15 mixed-gender) participated. Older siblings were TD (M=9.2 years, SD=2.01; 11 boys, 14 girls); younger siblings were diagnosed with ASD (M=6.4 years, SD=1.53; 24 boys, 1 girl).

TD-siblings completed:

- Sibling Relationship Questionnaire (SRQ; Furman & Buhrmester, 1985): measures Warmth/Closeness, Relative Status/Power, Conflict, and Rivalry. Items were rated on a 5-point Likert scale (5 indicates high levels of a factor, 1 indicates low levels).
- An open ended oral interview regarding sibling relationships. Each interview was transcribed and analyzed in a qualitative approach.

Results:

SRQ factor group means were within average range: Warmth/Closeness M=3.08 (SD=0.678); Relative Status/Power M=2.229 (SD=1.587); Conflict M=2.566 (SD=1.127); Rivalry M=2.9 (SD=0.466). This is in accordance with previous reports (Kaminsky & Dewey, 2001).

Content analysis of the interview data revealed eight categories: particularity of ASD sibling; disparities; conflict; negative reference; positive reference; similarity and closeness; TD-sibling's role; strengths of the ASD sibling.

Without being directly asked, 20% of TD-children chose to describe their siblings' strengths and advantages, and almost 50% described similarity and closeness they share with their siblings. 40% referred to disparities between them and their siblings, and 20% referred to difficulties and the particularity of their siblings. Only one child used the word 'autism' (*"I don't know if my mother told you, but he has autism"*). While the SRQ demonstrated a moderate level of conflict, interviews showed that conflicts can be characterized as a strong attribute in the relationships.

Conclusions:

- It is important to extend sibling research beyond biological questions to include sibling relationships.
- In line with previous research, our results reveal a generally positive perception of TD-children on their relationships with siblings with ASD.
- Qualitative analysis detected themes absent from the structured questionnaire.
- The study demonstrates the benefits of a mixed methods approach to better understand sibling relationships.
- Future studies will explore the connection between siblings' perception of relationships and actual behaviors during interactions.

180

185.180 SPARK Research Match: A Platform to Accelerate Research By Matching SPARK Participants with New Autism Studies

C. W. Lehman[1]*, J. K. Law*[2]*, J. Toroney*[2]*, B. Vernoia*[1]*, P. Feliciano*[1] *and W. K. Chung*[1]*, (1)Simons Foundation, New York, NY, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD*

Background: The Simons Foundation Powering Autism Research for Knowledge (SPARK) is a collaborative, online study that enrolls individuals with a professional diagnosis of autism and their family members into an autism research cohort. All participants consent to be contacted about future autism research studies. With over 90,000 engaged participants and over 30,000 with ASD, SPARK offers an unprecedented opportunity to facilitate autism research broadly by assisting researchers with study recruitment – one of the major challenges in conducting clinical studies (Denhoff 2015). SPARK features a research match (RM) process that supports external study data collection to facilitate research recruitment, requires bi-directional data sharing to enhance both SPARK data and researchers' studies and to minimize participant burden, and captures participant and researcher feedback to inform future RM studies.

Objectives: (1) Describe the research match process in SPARK (2) Report outcomes for completed studies

Methods: The RM process is divided into three stages: application, launch, and study close. All investigators seeking to recruit SPARK participants complete an application. Proposed studies are reviewed by the RM committee, comprised of research and recruitment experts, and scored based on research and engagement merit. During the pre-launch phase, the RM team works with the investigator to draft recruitment materials that fit the standard SPARK communications and to modify the study consent to allow for bi-directional data-sharing. For internet-based studies, SPARK has developed the infrastructure for online surveys and databases. During the launch phase, potentially eligible SPARK participants are notified by email about the new study. Participants can 'opt-in' to receiving additional information. For online studies, the RM platform supports electronic consent, data collection, and incentive distribution. For in person studies, participants complete an online data authorization and provide updated contact information, which are shared with the external study team for follow-up and study team contact. After study launch, response rates are closely monitored and adjusted to balance recruitment goals and participant experience. The final stage includes preparation and transfer of study data set (if applicable) and a summary RM report for the external research team with recruitment metrics. Participant and researcher feedback are captured at the close of the project. The SPARK team also works with researchers to prepare aggregate study results for communication to participants.

Results: As of October 2017, SPARK has received 10 applications. To date, 4 RM studies have launched (2 online, 1 in person, and 1 other) and over 10,000 SPARK participants were invited to participate in at least one RM study. Data from these initial studies demonstrated response rates as high as 60% and high participant satisfaction with the process and study topics. Implications for study recruitment and satisfaction based on project type (e.g. survey vs in person) will be presented. Additionally, feedback data from researchers and participants will be shared.

Conclusions: Overall, the research match process in SPARK benefits both researchers and participants by facilitating high quality research to help address important questions about autism, with the goal of improving the understanding, diagnosis, and treatment of autism and related disorders.

181 **185.181** Students with Autism Spectrum Disorder and Their Parents in the Transition into Higher Education: Dynamics in Parent-Child Relationships

V. Van Hees[1]*, H. Roeyers*[2] *and J. De Mol*[3]*, (1)Ghent University, Departement of Experimental, Clinical and Health Psychology, Ghent, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (3)Department of Psychology and Educational Sciences, Université catholique de Louvain, Louvain-La-Neuve, Belgium*

Background: The number of individuals with autism spectrum disorder (ASD) attending postsecondary education is growing. Compared to other disability groups, students with ASD in postsecondary education have reduced graduation rates, and face difficulties with managing the competing social and academic demands in postsecondary education, achieving appropriate time management and self-advocacy skills, and difficulties with regulating emotions and sensory issues. In addition to these challenges, many young adults with ASD lose the entitlement to formal supports services after they leave secondary education school. As a consequence, they rely on their parents who have to continue their role as the main source of support and care. This situation where parents hold persistent responsibility to provide support to their child may have a significant impact on family life. How the transition impacts on families caring for young adults with ASD has hardly been studied.

Objectives: The purpose of the present study was to gain a thorough understanding of how the higher education transition context impacts on dynamics in the parent-child relationship for students with ASD. In accordance with the aim of the study, we systematically investigated from a dialectic perspective both parents' and students' perceptions on college attendance, the perceived obstacles and the support needs, while focusing on the dynamic processes in the parent-child relationships.

Methods: Social Relational Theory formed the conceptual framework for this study as it represents an open-ended dialectical framework regarding dynamics in the parent-child relationship and provides guidance for exploring underlying micro processes of social transactions. Semi-structured interviews with senior students and first-year college students with ASD, their mothers and fathers (were analyzed based on grounded theory and dyadic analysis principles.

Results: Both parties were confronted with an abundance of challenges and experienced strong feelings of ambivalence, stress and anxiety. Differences in perspectives occurred regarding the construction of adulthood, the acquisition of autonomy, disclosure and subscribing to support services. These differences caused tensions in the parent-child relationship, hindering the transformation of the relationship into an adult-like mutual relationship.

Conclusions: This study was the first to examine the first-person accounts of students with ASD, their fathers and their mothers on a systemic within-family level. The dyadic interview analysis made it possible to carefully compare, reflect on and integrate the perspectives of the participating family members and in this way lifted our systemic understanding of the complexity of the transition process for families with a youngster with ASD. If the school setting, clinicians, and the wider network around the family, approach this complexity with mutual respect and understanding to both parents and the students with ASD, a strong partnership can be created which contributes to a more successful transition experience for these families. We emphasize the need for further clinical and educational reflection and research to forward our understanding on family functioning in families with a youngster with ASD.

182 **185.182** The Concept of "Autism" in Parenthood and in the Clinic. an Empirical Investigation.

D. Jacobs*, Centre for Biomedical Ethics and Law, KU Leuven, Leuven, Belgium*

Background:

The concept of autism is characterized by change and heterogeneity throughout history (Verhoeff, 2013) and throughout cultures (Kim, 2012). Moreover, it is unclear whether the research findings on ASD are translated into meaningful information for the clinic and for parents (and their children).

Objectives:

We aim at investigating the experiences of parents of getting an ASD diagnosis for their child, and the experiences of clinicians in using an ASD diagnosis. The final goal is to come to an ethical synthesis, grounded in the results of our empirical investigation, and in our systematic literature review on the topic.

Methods:

In our empirical study, we investigate how the autism concept is understood and experienced by parents and physicians. Parents who ask an ASD (autism spectrum disorder) diagnostic assessment for their child are interviewed at three different moments (Saldaña, 2003). Physicians working with children with (a presumption of) ASD are interviewed once.

Results:

I will present the results of the Interpretative Phenomenological Analysis (IPA) of the clinician and parent interviews (Smith, Flowers, & Larkin, 2009).

A preliminary interpretation of these empirical results argues that the most common research view on ASD appears to be different from the interviewed physicians' view.

Such a discussion secondly purports that the interviewed physicians and parents experience several advantages connected to a diagnosis of ASD. These advantages appear to be closely linked to the way our society is organized in distributing mental services, and to the way people in our society view and estimate children and parents.

Conclusions:

Evidence-based medicine is not the only guiding principle for clinicians when dealing with ASD.

Besides, the experienced advantages of a diagnosis are culturally embedded, and when also possible disadvantages are considered, the question arises as to whether giving a categorical diagnosis of a medical disease is the most favorable way to deal with autism-like behaviors and worries, both for clinicians and for parents and children.

183 **185.183** The Desirability of Autistic Males' Online Dating Profiles.

*D. Rees-Evans[1], J. Gavin[1] and **M. Brosnan**[2], (1)University of Bath, Bath, United Kingdom, (2)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland*

Background:

A lack of success through traditional, face-to-face dating has led some adults with Autism Spectrum Disorder (ASD) to pursue relationships through online dating. The online dating profile is a significant gateway to the initiation of dating. Research within the general population has suggested that trust is a key variable influencing the desire to interact further with an individual (our definition of desirability) and consistency within the online dating profile has been identified as a key influence of trustworthiness.

Objectives:

To compare the relative impact of both typically-desirable and autistic attributes and interests upon perceived desirability and trustworthiness in online dating profiles.

Methods:

Participants were 111 females who self-identified as 'seeking a man' through online dating. The mean age was 25 years (sd=7, range = 18-57). Participants were recruited through online advertisements and asked to rate the desirability and trustworthiness of a male in an online dating profile (both averaged, range 1-5). Participants also rated their current level of autism knowledge from 1 'never heard of it' through to 4 'expert'.

Four online dating profiles were constructed based on the format of the world's most popular online dating site. All profiles shared generic average physical information such as body type, height and a photo previously rated to be average. The profiles varied in a free text section. The typical attributes (upbeat, confident, good sense of humour) and interests (bike riding, photography, kids and listening to music) were taken from those listed as desirable by the online dating site. The autistic attributes (honest, shy and kind of nerdy) and interests (exercising, watching TV, technology and gaming) were taken from an analysis of autistic online dating profiles. Participants read and rated one of the following combinations:

1. a) Autism Attributes, Autism Interests (AA-AI)
2. b) Typical Attributes, Typical Interests (TA-TI)
3. c) Autism Attributes, Typical Interests (AA-TI)
4. d) Typical Attributes, Autism Interests (TA-AI)

A MANCOVA was conducted on desirability and trustworthiness by condition, controlling for level of autism knowledge.

Results:

Desirability and trustworthiness significantly correlated with each other ($r=.36$, $P<.001$). There was a significant main effect for condition for desirability ($F(3,106)=3.50$, $p<.05$) but not trustworthiness ($F(3,106)=2.01$, ns). The Figure highlights that the consistent profiles were more desirable than the inconsistent profiles, interestingly the consistent autistic profile was the most desirable.

Conclusions:

An autistic profile describing autistic attributes and interests was rated as being comparably desirable to a profile describing typically desirable attributes and interests. Whether autistic or typical, presenting attributes and interests that were consistent with each other was more desirable than inconsistent profiles. Previous research has suggested that this effect is driven by perceptions of trustworthiness, but the present study does not fully support this, although trustworthiness and desirability were correlated with each other. The results would suggest that autistic online daters should have profiles consistent in their attributes and interests, and not embed profiles with typically desirable features. It should be noted that this is relative, the consistent profiles have a mean around the midpoint of the 1-5 scale.

184

185.184 The Differential Impact on Parents of Two Different EIBI Programs in Canada

B. D'Entremont[1], *H. E. Flanagan*[2], *I. M. Smith*[3], *N. Garon*[4], *W. J. Ungar*[5], *K. Tsiplova*[5], *C. Waddell*[6], *S. E. Bryson*[7], *J. den Otter*[8], *N. Leger*[9] *and P. McDonnell*[10], *(1)University of New Brunswick, Fredericton, NB, Canada, (2)IWK Health Centre, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (4)Mount Allison University, Sackville, NB, Canada, (5)University of Toronto / The Hospital for Sick Children, Toronto, ON, Canada, (6)Simon Fraser University, Vancouver, BC, Canada, (7)Dalhousie University, Halifax, NS, Canada, (8)Education and Early Childhood Development, Fredericton, NB, Canada, (9)Department of Education and Early Childhood Development, Government of New Brunswick, Fredericton, NB, Canada, (10)McDonnell, Cartwright, and Associates, Fredericton, NB, Canada*

Background: Research supports the effectiveness of early intensive behavioural intervention (EIBI), including community-based programs, for preschoolers with autism spectrum disorder (ASD; Reichow & Wolery, 2009). Less is known about parents' experiences with these programs. Research suggests that parent satisfaction, increased parental self-efficacy and decreased family stress can lead to families remaining in treatment and to improved child outcomes (Karst & van Hecke, 2012). However, longitudinal data are lacking and we are aware of no research comparing the impact of different early intervention programs on parents. Our Preschool Autism Treatment Impact study addressed this by comparing cost-effectiveness and treatment impact of two provincial EIBI programs, including effects on parents.
Objectives: To compare parent satisfaction, parental self-efficacy, and level of family stress for parents of preschool children with ASD, served by two publicly-funded province-wide EIBI programs, over the duration of intervention.

Methods: Data were collected at intervention onset (T1) from 269 parents from Province A and 367 parents from Province B. The programs differ in several ways. In global terms, program A adheres to a naturalistic, less-intensive model with a focus on parent training, whereas program B is similar to more conventional community-based EIBI. Parents completed a questionnaire measuring parenting self-efficacy in the areas of communication and social skills, daily living skills, and challenging behaviour, as well as a single-item measure of stress/crisis level at T1, after one year of intervention (T2) and at school entry (T3). Parents also completed a satisfaction survey at T2 and T3.

Results: Controlling for T1 self-efficacy (higher in Province A), parental self-efficacy increased similarly in all 3 domains from T1 to T2 for both provinces (see Table 1). In Province A, this improvement was maintained from T2 to T3 for Communication/Social Skills and Daily Living Skills. Self-efficacy for Challenging Behaviour declined from T2 to T3, but not to T1 levels. Responses at T3 for Province B were insufficient to include in longitudinal analyses. Family stress/crisis level decreased from T1 to T2 ($F_{(1,131)} = 16.28$, $p < 0.001$) with no differences between provinces. Results suggest parents were experiencing some difficulties/stress but were coping. Parents were generally satisfied with both EIBI programs. Responses across provinces were compared at T2 (see Table 2). Although response patterns were similar, parents in Province A reported more satisfaction with the location of services, their child's team's coordination with other services and support of parent involvement, their learning of helpful strategies, and the high quality of treatment. Satisfaction remained stable from T2 to T3 in Province B; Province A did not provide EIBI services between T2 and T3.

Conclusions: EIBI programs have a positive impact on families. This is true even when programs differ in key aspects including intensity, range of intervention techniques employed, duration, and service delivery model. Although only Province A specifically used a parent training model, parents from both provinces increased similarly in self-efficacy and decreased similarly in relation to stress/crisis. Some differences in parent satisfaction, favouring Province A, suggest that focusing on, and involving, parents may increase family satisfaction.

185

185.185 The Effects of Short-Term, Intensive Pivotal Response Treatment Education on Parent Self-Efficacy and Stress for Families Newly Diagnosed with Autism

K. Oliver[1], *R. L. Koegel*[2], *K. Byrne*[3] *and H. Wenzel*[1], *(1)Koegel Autism Center, Santa Barbara, CA, (2)Stanford Medical School, Stanford, CA, (3)University of California, Santa Barbara, Koegel Autism Center, Santa Barbara, CA*

Background: Parent involvement in the treatment programming of their child with autism spectrum disorder (ASD) is widely recognized as an important component for successful outcomes. Parent education programs that provide training in Pivotal Response Treatment (PRT) to families of young children with ASD have been shown to improve both child and parent outcomes. PRT is an evidence-based treatment approach that uses motivational strategies to target social communication. Benefits of educating parents in PRT include increases in child verbalizations, parent and child positive affect, and decreases in parent stress.
Objectives: There seems to be a paucity of research regarding the impact of intensive individualized parent education programs in PRT on additional dimensions of parent well being. The research also appears limited on the effects PRT programs have on parents of children who are newly diagnosed with ASD. Parent education may be particularly important for these families, as this is a period of time when parents often face great uncertainty and distress. Thus, the objective of this study was to examine how a brief, individualized parent education program impacted parent self-efficacy, hope, and stress for parents whose child had a recent diagnosis of ASD, both immediately after the treatment program and long-term.

Methods: Using a concurrent multiple baseline experimental design across participants, this study examined outcomes of an intensive 5-day, 20-hour parent education program in PRT for families whose child has recently received a diagnosis of ASD. Parents learned to implement the motivational components of PRT through observation of a clinician, practicing with their child, and receiving feedback on their implementation. The education program was characterized by a parent-clinician partnership model and used a strength-based approach to teach parents to implement PRT with their child. Standardized assessments, behavioral observation data, and brief interviews with parents were used to analyze parent measures, including stress, self-efficacy, and hope. Parent fidelity of PRT implementation was also collected, in addition to child functional utterances.

Results: Results from the pilot study indicated that all parents showed a decrease in observed stress levels and an increase in observed confidence levels after participating in the parent education program. Further, parents reported increased confidence in teaching their child and getting their child to communicate (i.e., self-efficacy) following the treatment program.

Conclusions: Brief, intensive PRT parent education appears to have positive effects on multiple constructs related to parent well being, such as self-efficacy, hope, and stress, for parents whose child recently received a diagnosis of ASD. This approach is likely an effective way to provide parents with short-term education on how to implement an evidence-based treatment with their child while they await more intensive or comprehensive services.

186 **185.186** The Influence of Coparenting Support on Fathers of Children with Autism

*J. L. Bloom and **M. N. Gragg**, University of Windsor, Windsor, ON, Canada*

Background: Fathers of children with Autism Spectrum Disorders (ASD) experience a great deal of parenting stress, and report having to prioritize their coparenting relationship above their marital relationship, to appropriately care for their children. For fathers of typically developing children (TD), supportive coparenting relationships are related to fathers' well-being, self-efficacy, and involvement, however, these relationships have not been directly studied with fathers of children with ASD. Self-determination theory suggests that individuals who are supported and confident in their abilities for a behaviour will be more intrinsically motivated to engage in this, will enjoy this more, and will have greater well-being. For fathers of children with ASD, supportive coparenting relationships may influence their involvement, in both play and child-care, and their well-being.

Objectives: The present study investigated the quality of coparenting support received by fathers of children with ASD and the influence of this on fathers, including: involvement in play, involvement in child-care, motivation for involvement, and parenting stress. Fathers' qualitative responses to 3 survey questions and 6 questions during an optional telephone interview were also examined.

Methods: An online survey was completed by 66 fathers of children with ASD aged 4 to 11 years. The survey included a child ASD screening measure, and questions regarding fathers' coparenting relationship quality, involvement in play and child-care, satisfaction and motivation for involvement, and parenting stress. Participants (M_{age} = 40.2) were primarily biological fathers, married, Caucasian, from Canada, with a post-secondary education, and living in the same home as their children (sons = 54) with ASD (M_{age} = 6.9). The majority of fathers lived with their coparent (M_{age} = 37.8) who were primarily spouses. An optional phone interview was conducted with 7 participants, including 6 questions related to their involvement, their coparenting support, and their well-being.

Data collection is ongoing and it is expected that, in total, 120 fathers will complete the online survey and 20 fathers will complete the optional phone interview.

Results: Overall, fathers reported supportive coparenting relationships (M_{total} = 5.25, subscales ranged from M = 4.6 to M = 6.2, on a 7-point Likert scale). Multiple regression analyses revealed that greater coparenting relationship quality predicted lower parenting stress, and greater satisfaction with involvement in both play and child-care. In turn, greater satisfaction with involvement in play predicted more frequent involvement in play. Greater satisfaction with involvement in child-care similarly predicted more involvement in child-care. Responses to open-ended questions on the survey and phone interview will be analyzed using thematic analysis.

Conclusions: Results suggested that the support fathers receive from their coparent can have an important influence on fathers' parenting stress and their involvement with their children with ASD. These findings are consistent with the literature for fathers of TD. Given that raising children with ASD may place a strain on the marital relationship, these results highlight the value of supportive coparenting relationships for fathers of children with ASD. Implications for maintaining supportive coparenting relationships and incorporating coparenting dynamics into parent-training programs will be discussed.

187 **185.187** The Interest of Adolescents with Autism in Future Careers Involving Technology

ABSTRACT WITHDRAWN

Background: In the US, students with autism have some of the poorest post-school outcomes of any disability category, according to the National Longitudinal Transition Study-2. Finding opportunities to match their skills and interests to sustainable employment is a priority. It has been reported that many individuals with autism are attracted to technology, in particular screen-based technology, especially for entertainment. For most young people, their interests often lead to future careers. Since careers involving technology skills are in high demand, technology-related careers hold promise for improving the adult outcomes for students with autism. However, little is known about this subject.

Objectives: The primary purpose of this study was to understand what interest adolescents with autism have in a future career using technology. Also, to understand specifically which areas involving technology they are interested to pursue in higher education.

Methods: This study used a paper survey with 275 high school students with autism from 30 high schools spread across 3 states in the US. The majority of participants are male (87%), white (72%), without ID (93%), and on track to graduate high school with a regular diploma (100%).

Results: Student survey participants were asked about their interest in using technology in their future. The majority (75%) said they would like to have a job using technology. Most are considering going to college (96%) and 65% would like to study a technology-related subject in college. Video game design was the most popular technology related subject followed by computer science, engineering, and web design.

Conclusions: Cultivating student interest in technology early during middle and high school might help to ensure fulfilling their future interest in studying technology-related subjects at university and working in occupations using technology.

188 **185.188** Online Learning : A Good Fit for Students with Autism?

ABSTRACT WITHDRAWN

Background: Adolescents with autism are heavy users of technology for entertainment. What is not well known is how they use it to support learning. Navigating the high social demands of high school can be overwhelming for many students with autism causing stress and anxiety. Online learning may be a way for these students to take courses, in particular in subject areas of interest that may not be available in their local high school, thus helping to better prepare them for life after high school. However, there is very little literature on the compatibility of online learning for students with autism. Taking courses from the comfort of a quiet classroom dedicated to online learning, or even from home, may be another way to help adolescents with autism better transition to higher education and/or careers of interest.

Objectives: The purpose of this study was to explore the experiences of online learning for secondary students with autism. Specifically, in what ways do they find online learning beneficial and what subjects are they taking.

Methods: This study used a paper survey with 275 high school students with autism from 30 high schools spread across 3 states in the US. The majority of participants are male (87%), white (72%), without ID (93%), and on track to graduate high school with a regular diploma (100%).

Results: This study found that while only 27% of participants had an online learning experience, 52% indicated they were favorably disposed to taking one in the future. Of those students who had an online experience, the majority found it beneficial mostly due to their ability to control the amount of time they needed to learn. 55% said they liked learning online because they could take as little or as much time as they needed to work on the course and 48% said they liked it because they could work on it anytime they wanted to. Regarding the reduction in social interaction through online learning, only 19% said they liked it because they did not have to interact with the teacher and 18% because they did not have to interact with other students. Most participants took courses in subjects related to science and math.

Conclusions: Students with autism who have experienced online learning find it beneficial for the control it gives them over when and the amount of time they devote to the learning. Reasons related to a reduction in social interaction were less important. Online learning has potential to help young adults with autism to ease into higher education or to fill gaps in their knowledge using online courses as they transition to adulthood.

189 **185.189** Transition from High School: Parent Stress and Family Quality of Life When Their Child Has Autism Spectrum Disorder

J. Best *and B. D'Entremont, University of New Brunswick, Fredericton, NB, Canada*

Background:

Research examining the transition from high school has found that parents of children with developmental disabilities report more stress and fewer rewards than parents of typically developing children (Glidden & Jobe, 2007) and that parent stress reported by parents of children with developmental disabilities is predicted by parent coping (Glidden & Natcher, 2009) while family quality of life (FQOL) is predicted by child problem behaviours, support needs, and religious faith during this time (Boehm, Carter, & Taylor, 2015). Unfortunately, these studies either did not include parents of children with ASD (Glidden & Jobe, 2007; Glidden & Natcher, 2009) or did not include any transition-specific measures (Boehm et al., 2015). Unlike the United States, where previous research was conducted, no federal policy exists governing this transition in Canada nor has any research been conducted in Canada on this transition.

Objectives:

To examine the contribution of parent coping, child behavioural symptoms, presence of a written plan for the transition out of high school, and parent satisfaction with the transition process, to parent stress and FQOL during the transition process. The research questions explored were: Do parental coping strategies predict parent stress and FQOL during this transition? Do both positive and problematic child behaviours predict parent stress and FQOL related to the transition out of high school? What is the contribution of having a transition plan and transition satisfaction over and above parent coping and child behaviours during this transition?

Methods:

Fifty-seven parents or guardians of a child with ASD completed an online survey containing demographic information and the following measures: Brief COPE (Carver, 1997), Nisonger Child Behaviour Rating Form (Aman, et al., 1996), Transition Daily Rewards and Worries Questionnaire (Glidden & Jobe, 2007), the Beach Centre Family Quality of Life Scale (Hoffman et al., 2006), parent satisfaction with the transition, and presence of a written transition plan. A series of hierarchical multiple regression with child behaviours and coping entered as on the first step, and transition plan and satisfaction on the second were used to predict the dependent variables of FQOL and parent stress.

Results:

Parent coping and child behaviour symptoms independently predicted FQOL and parent stress. Importantly, having a written transition plan predicted better satisfaction with disability related supports and fewer worries about community resources, while satisfaction with the transition process predicted greater family emotional well-being. These transition details predicted scores over and above parent coping and child behaviours. Finally, 82.5% of parents reported that their child did not have a written transition plan for the transition out of high school and only 16% reported being satisfied with their child's transition out of high school.

Conclusions:

This study highlights how the family's experience of the transition process plays an important role FQOL and parent stress during this time. Further, it highlights an area for critical future research. With few parents reporting satisfaction or the presence of a transition plan, future research should aim to understand factors that affect the resources accessed and satisfaction of parents in Canada during this time.

190 **185.190** What's It like to Have a Sibling with Autism: Experiences of Typically Developing Sibling from New Delhi, India.

D. Taneja[1,2] *and S. P. K. Jena*[3]*, (1)Action For Autism, New Delhi, India, (2)Applied Psychology, Delhi University, New Delhi, India, (3)Delhi University, New Delhi, India*

Background: Having a person with autism in the family, can be challenging for all members, including the typically developing siblings of the person with autism. In most communities, parents of children with similar conditions have the opportunities to interact while availing services for their child or by participating in parent support groups. However, it is very common for typically developing siblings to not get an opportunity to share their experiences with other siblings. They go through life feeling 'alone', often resenting their sibling with disability, and not fully understanding the implications of having a brother or a sister with autism. This is especially of great concern in low and middle income countries like India, where no state support is as yet available, and the unspoken cultural expectation is that the typical sibling will care for the autistic sibling once the parents are no more. To understand the experiences of typically developing siblings of individuals with autism, we conducted a peer support programme based on US based sibling support model *Sibshops.*

Objectives: The present paper seeks to highlight the feelings and emotions felt by the typically developing siblings of children with autism. It evaluates the impact of a peer support programme on the typical siblings' feelings and emotions towards the disabled sibling.

Methods: Nine typically developing siblings participated in a peer-support programme at Action for Autism, the National Centre for Autism in India. Twelve sessions of 3-4 hours each were conducted over a period of four months. The sibling support model *Sibshops* was adapted for the Indian culture and was a mix of fun and discussion activities focussing on peer support. The programme was a safe place for siblings to share their feelings with other sibling participants. The typically developing siblings as well as their parents were interviewed at the beginning and at the end of the programme. In addition, activities of the peer-support programmes were designed to capture different emotions and feelings towards the typically developing siblings. These discussion activities were audio recorded and transcribed. Analysis was conducted to understand various emotions and feelings of typically developing siblings of individuals with autism.

Results: Findings indicate positive impact of the programme on various attributes of the typically developing sibling. Typically developing sibling as young as ten years of age reported feeling embarrassed, guilty, angry, worry towards their sibling. They also expressed various positive emotions such as pride and happy.

Conclusions: This is one of the few studies in a low resource country, which focusses on typically developing siblings of children with autism. Results support the need for such group interventions and controlled evaluation of sibling support groups to improve mental health and functioning of typically developing sibling. It has implications for running sibling support groups in low resource countries like India to address the needs of and the growing expectations from typically developing siblings of individuals with autism.

191 **185.191** A New Tool to Assess Family Context Features That Promote the Early Development of Young Children at-Risk for ASD

A. Aranbarri[1], *A. C. Stahmer*[1], *J. Acha*[2], *E. Arranz*[2], *M. E. Miller*[1], *M. R. Talbott*[1] *and S. Rogers*[3], *(1)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (2)Department of Basic Psychological Processes and Their Development, Psychology Faculty, University of the Basque Country UPV/EHU, Donostia-San Sebastian, Spain, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

Background: Recent studies confirm the importance of a high-quality family context for promoting children's early development, even after adjusting for socioeconomic variables (e.g., Rijlaarsdam et al., 2013). Although these studies have examined the role of home environment and family context in typical development, there is likely an effect for children with Autism Spectrum Disorder (ASD) as well. This is especially true as children with ASD often participate in early intervention programs (EIPs) at home setting, with families serving as an integral part of the intervention team. The *Etxadi-Gangoiti Scale* is a recently published, validated measure designed to assess the family context of typically developing children (Arranz et al., 2014; Velasco et al., 2014). However, some questions are inappropriate for children with ASD (see examples in Table 1).

Objectives: To adapt the *Etxadi-Gangoiti Scale* for use with families of young children with ASD and assess comprehension, clarity, and familiarity at the community level, as well as feasibility in an EIP.

Methods: We adapted the scale considering early ASD developmental features and in-home EIP delivery. Four experts in early development and ASD analyzed the scale content. We conducted two community focus groups: (1) 6 EIP providers (psychology, education, and nursery disciplines) serving urban and rural areas, and low-medium resource children with ASD. (2) 5 parents of children with ASD (4 mothers, 1 father; 3 African American, 2 Hispanic) living in urban areas. Forty percent reported living in somewhat unsafe neighborhoods. Both groups scored each item for the level of comprehension, clarity, and familiarity using a 6-point Likert scale (1=*Very hard to understand*, 6=*Very easy to understand*). Items receiving a score of 4 (*somewhat easy to understand*) or lower were discussed and edited as a group to obtain consensus. Lastly, edited items were scored a second time using the same metric. Providers scored the feasibility of the scale in an EIP.

Results: The adapted scale includes 62-items in two subscales: a) caregiver self-report (47 items); b) observational assessment for EIP providers (15 items). The scale measures family features associated with promoting early development, summarized by 8 indicators (see items' distribution across indicators and subscales in Figure 1): 1) Home and physical environment; 2) Presence of toys to promote development; 3) Family routines, structure and habits; 4) Parent behaviors promoting socio-emotional, communication, play, and cognitive development; 5) Exposure to peers; 6) Family and social support 7) Level of family stress; 8) Caregiver's knowledge and exposure to disability. Parents' rated 14 items (30%) with a score of 4 or lower. After editing, they scored 5 or higher for all items. The Provider group edited 8 items (53%) based on initial scores, and after discussion, all items reached the highest comprehension score of 6. Regarding the tool's feasibility in EIPs, 83% of providers scored "*strongly agree*."

Conclusions: Existing home and family assessment scales are not appropriate for young children with ASD feasible for in-home EIPs. This scale may help us understand how to individualize ASD treatment and parent coaching strategies for unique family features and environments.

192 **185.192** Autistic Mothers' Experience of Parenthood

S. Hampton[1], *R. Kenny*[1], *R. Holt*[1], *B. Auyeung*[2], *C. Allison*[3] *and S. Baron-Cohen*[3], *(1)University of Cambridge, Cambridge, United Kingdom, (2)University of Edinburgh, Edinburgh, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom*

Background: Little research has explored how autistic women navigate the challenges involved throughout parenthood. Findings from one study, as well as anecdotal accounts, suggest that autistic mothers do not receive sufficient support and feel judged and misunderstood by medical and education professionals (Pohl et al., 2016). It is therefore important that research addresses not only the challenges autistic mothers face but also their strengths. For example, it is possible that autistic mothers may be well placed to support autistic characteristics of their children and may be particularly strong at providing routine and security for their children.

Objectives: The study aimed to identify the potential strengths of being an autistic mother, as well as areas where support is required.

Methods: The study took a qualitative approach, aiming to provide an in depth, nuanced account to complement the prior quantitative study on the topic. Three autistic mothers attended a focus group concerning their experience of parenthood. The focus group was semi-structured and guided by questions concerning 5 main areas: parenting challenges, parenting strengths, approaches to parenthood, parent-child relationships and support needs. The ages of the mothers ranged from 40 to 43 years old and the ages of their children ranged from 4-22 years old. All of the mothers had at least one child with autism and at least one child without autism.

Results: A process of inductive, thematic analysis revealed 5 key themes. Firstly, parents identified strengths associated with being an autistic mother, including skills in practical aspects of parenting, advocating for one's child and the ability to understand their autistic children due to their own diagnosis. Secondly, parents highlighted parenting challenges, including difficulties engaging in creative play and difficulty modelling social skills for their children. Thirdly, mothers felt a strong sense of others' judgement. They reported feeling judged by professionals, by whom mothers felt blamed for their children's challenges, in addition to a strong pressure to conform to normative parenting expectations. These expectations included expressing emotion in neurotypical ways and emulating normative ideals of the 'perfect' family life. Fourthly, mothers described their own non-normative approach to parenting. They expressed awareness of not conforming to the ideals of motherhood and described a different approach to mothering in which their concern and affection for their children, while just as strong as that of neurotypical mothers, are differently expressed. Finally, mothers showed dissatisfaction with the support available, which often involved being required to attend stressful social situations and endure scrutiny from professionals. Mothers expressed a desire for non-judgemental mentoring and peer support.

Conclusions: These findings point towards the need for greater understanding of parenthood for those with autism amongst professionals. Our findings suggest that traditional forms of support may not be helpful for autistic mothers and that systems of peer support may be particularly beneficial. This qualitative study could be followed by a quantitative survey to test if the themes generalise to a larger sample. The findings have important policy implications for how best to support autistic mothers.

193 **185.193** Caregiver Stress and Comorbid Autism Spectrum Disorder and Epilepsy

A. Aitken[1]*, C. A. McMorris*[2]*, D. Dewey*[3]*, J. Buchhalter*[4] *and K. Smyth*[5]*, (1)School and Applied Child Psychology, University of Calgary, Calgary, AB, Canada, (2)Werklund School of Education, University of Calgary, Calgary, AB, Canada, (3)University of Calgary, Calgary, AB, Canada, (4)Department of Pediatrics, Cumming School of Medicine, Alberta Children's Hospital Research Institute, University of Calgary, University of Calgary, Calgary, AB, Canada, (5)Department of Pediatrics, Cumming School of Medicine, Alberta Children's Hospital Research Institute, University of Calgary, Calgary, AB, Canada*

Background: Nearly one third of children with Autism Spectrum Disorder (ASD) have comorbid epilepsy (EP), with these individuals displaying more severe symptoms in areas of social impairment, challenging behaviours, motor difficulties, and other medical complications. Significant levels of stress have been well documented among caregivers of children with ASD, as well as among families of children with EP. However, to date there is little research investigating the stress that caregivers of children with comorbid ASD and EP experience. Caregivers of children with ASD have reported familial, financial, and mental health issues. Given that children with comorbid ASD and EP present with more severe symptoms across a wide range of functions, it is important to develop a better understanding of the experiences of caregivers of children with ASD and EP. Determining caregiver's experiences will address a significant gap in research literature and will assist health practitioners in meeting the needs of these families.

Objectives: The project has two primary aims: 1) to examine the quality of life, stress and parenting experiences of caregivers of children with ASD and EP; and 2) to investigate the relationship between caregivers' quality of life and the clinical profiles of their children/youth with ASD and EP. It is hypothesized that caregivers of children and youth with ASD and EP who have severe developmental delays, behavioural problems, and additional medical complications will report higher levels of stress and poorer quality of life.

Methods: Participants are recruited from the Autism and Epilepsy Clinic, a specialized clinic at the Alberta Children's Hospital (ACH; Alberta, Canada) that provides seizure management to children and youth with ASD and EP. Since its establishment in 2013, this clinic has served approximately 200 children. Participants must have a diagnosis of ASD and EP. To determine the clinical profiles of the children, chart reviews will be completed through the electronic clinical note used by health practitioners in the Autism and Epilepsy Clinic. This innovative note includes detailed information on the age of seizure onset, seizure type and frequency, medications/treatments, medical diagnoses, cognitive functioning, and other presenting problems. Children will also participate in a comprehensive neuropsychological assessment, with measures of cognitive functioning (WPPSI-IV; WISC-V), executive functioning (NEPSY-II), and behaviour (BASC-3; CARS-2). The Kidscreeen-52, and PSI-4 will be used to assess the children's and caregivers' current quality of life and stress. Data will be analyzed using basic descriptive statistics, and will be examined in relation to caregiver measures.

Results: We anticipate over 50 completed assessments by Spring 2018.

Conclusions: The present study will examine the association between the clinical profiles of children and youth with ASD and EP, and their caregivers' quality of life and stress. It is important that families have a clinical support network that understands their unique situation and can provide the necessary services for these children. Findings from the present study will help to inform the development of caregiver resources and aid health practitioners in improving the outcomes for these children and their caregivers.

194 **185.194** Challenging Behavior in Preschoolers with ASD

C. K. Toolan[1]*, A. Holbrook*[2]*, S. Y. Shire*[3]*, R. Landa*[4]*, T. Smith*[5] *and C. Kasari*[1]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)University of California Los Angeles, Los Angeles, CA, (3)University of Oregon, Eugene, OR, (4)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (5)University of Rochester Medical Center, Rochester, NY*

Background:

Children with ASD often present challenging behaviors (CBs) across home and school contexts. CBs impact caregiver stress and mental health (Davis & Carter, 2008; Hayes & Watson, 2012). CBs in school contexts affect teachers' instructional efforts (Carr & Robinson, 1991) and predict burnout (Hastings & Brown, 2002).

While there is much literature on CBs with school-aged children and youth (Lecavalier et al, 2006), there is less on preschoolers, particularly those with low rates of communication. These children may be at high risk of exhibiting CBs due to difficulty communicating their wants and needs. Additionally, much of the existing research is cross-sectional, with few examining CBs longitudinally.

Objectives:

1. Characterize parent- and teacher-reported CBs in preschoolers with ASD
2. Examine change in CBs over a 6-month period

Methods:

This study used baseline data from a social communication intervention RCT. Preschoolers (n=145) who used <30 spontaneous words at entry received 6 months of communication interventions. Parents received weekly training in intervention for 2 months. Treatment groups were combined since both targeted communication skills within intervention.

At entry and exit, parents completed the Home Situations Questionnaire-PDD (HSQ, 25 items), which assesses behavioral noncompliance in everyday settings. Parents were asked to endorse whether their child exhibited noncompliance in a range of situations (e.g., when transitioning between activities). Parents were also asked to rate the severity of their child's behavior for endorsed items (1=mild to 9=severe). In addition to total scores, subscores were calculated for the number and severity of socially inflexible vs. demand-specific CBs (Pelletier et al, 2006). Socially inflexible CBs included situations where children exhibited low adaptability to non-routine situations, while demand-specific CBs occurred when direct demands were placed on the child.

Teachers completed the School Situations Questionnaire (SSQ, 9 items), which is the HSQ analogue for school contexts (e.g., during free-play time in class). Total number of CBs and severity scores were calculated for entry and exit.

Results:

Table 1 includes descriptives for the number and severity of CBs reported by parents and teachers. HSQ and SSQ scores were not correlated.

Paired sample t-tests with corrections were conducted to examine change in number and severity of CBs over time. There were no significant changes in the number of CBs reported by parents or teachers. However, there were significant decreases in HSQ total severity (p=.004), HSQ socially inflexible severity (p=.001), and SSQ total severity (p=.005).

At entry, 50% of children presented clinically severe CBs on HSQ (2 SDs above normative mean from original HSQ; Altepeter & Breen, 1989), which reduced to 39% of children at exit. The change in proportion of children with clinically severe CBs was significant (p<.037).

Conclusions:

Parents and teachers both reported decreases in CB severity over time. Additionally, the decrease in children's CB at home was clinically significant, with fewer children scoring at elevated levels by exit.

This study confirms that CB is prevalent in preschoolers with ASD and limited language, but shows that CB decreases while children are in intervention to improve their communication.

195

185.195 Families Structure and Children with Autism: Population Estimates and Comparisons Using the United States' National Health Interview Survey

K. Hamre, *School of Social Work, Indiana University, Bloomington, IN*

Background:

It is important to understand the unique experiences of families who have a child with autism spectrum disorder (ASD). While much research in the area of autism has focused on children, comparatively less is known about the family experience. Understanding that a child's outcomes directly relate to the well-being and ability to adapt of their family, and drawing on family stress adaptation theory, this study investigates the makeup of families in which children with ASD reside, making comparisons to families with a child without a reported diagnosis of ASD.

Objectives:

The purpose of the study was to 1) develop population estimates of various family structures for children with ASD, 2) compare family structure population estimates with that of the general population; and, 3) model the effects of ASD on different family structures, while controlling for key variables.

Methods:

This study utilized the United States Centers for Disease Control and Prevention's 2014 and 2015 National Health Interview Survey (NHIS). This survey is a nationally representative, annual, cross sectional, household survey of families in the United States. The sample includes 22,697 families with children ages 3 to 17, of which 489 reported having a child with a diagnosis of ASD. Population estimates and standard errors were constructed and statistically compared to the general population and logistic regression was used to model the effects of ASD on family structure.

Results:

Findings include population estimates across family structures with children with a reported ASD diagnosis. Findings indicate 41.5% of children with ASD live in two parent families while 19.1% of children with ASD live in single parent families. More granular family structures are also investigated, including single mothers, single fathers, and cohabitating partners. Key findings include statistically significant differences between the population estimates of the ASD and non-ASD family structures. Among the findings, the results show an estimated 16% of children with ASD live in a home with a single mother, compared to 13.6% of children with no reported ASD diagnosis. In addition, logistic regression model results reveal that children with ASD have lower odds of living in a two-parent household. Children with ASD were found to have higher odds of living with a single mother compared to children without ASD. These logistic models controlled for a number of factors, including race, parent education, and socioeconomic status.

Conclusions:

The data indicates that families with children with ASD are having different experiences than families with children without an ASD diagnosis. This study presents population estimates across family structures for children with ASD in the United States, and makes comparisons to the general population. These results have implications in policy and practice for families with children with autism spectrum disorder.

196

185.196 Narratives about Self from High Functioning Autistic Adults in India

N. Singhal[1], *D. Taneja*[1], *M. Barua*[1], *T. Behl*[1], *R. Pradhan*[1], *T. Daley*[2] *and T. S. Weisner*[3], *(1)Action For Autism, New Delhi, India, (2)Westat, Durham, NC, (3)UCLA, Los Angeles, CA*

Background:

Autism in India remains a highly stigmatized condition, and many adults with high functioning autism continue to be undiagnosed and/or hidden. Even once the diagnosis is received, parents and therapists often do not disclose or share the diagnosis with the individuals with autism. So, what do our young people know about their autism? How do they perceive and understand themselves and their differences? Not many studies have explored this from the perspective of people with autism. The RAFIN Adult Study is the first to systematically examine adults with ASC in India.

Objectives:

This paper reports initial data on explanations by high functioning adults about their similarities and differences and their understanding of the reasons behind them.

Methods:

Thirteen high functioning adults with ASC were interviewed in their homes. The interactions with the adults were carried out through semi-structured interviews in the preferred language and lasted for about 2-3.5 hours. Amongst several other topics, we discussed the individual's understanding of their own self, their perceptions of similarities and differences from others around them, the nature of these differences (if any), as well as the kind of support they may like. This data is a part of a larger study of 54 adults and their families in Delhi & NCR region where we spoke to adults and their families about their journey since receiving the diagnosis as well as plans for the future.

Results:

Almost all participants had specific thoughts about how they were similar to and different from non-autistic people. The responses were categorised in various themes, such as concrete attributes, personality attributes, interests and preferences, specific skills, diagnoses, disclosure about diagnoses, strengths and limitations of being different.

Conclusions:

In one of the first studies of adults with autism in India, the authors present self-reports of verbally fluent adults with ASC about their understanding of their similarities and differences.

The study highlights that people on the spectrum are aware of their differences – some as early as primary school. However, an understanding and explanation of this difference comes much later, if at all. Most participants in our sample needed further clarity in understanding their difference.

The study emphasizes the need for active involvement of people with ASC in all life aspects, including research and interviews, aimed at understanding their unique life experiences; need for development of self-report measures and interview strategies; and most importantly the process of disclosure of diagnosis to individuals with autism.

197

185.197 Parental Perceptions of Their Healthcare Experiences & Future Need for Children / Young People with Autism in the U.K.

A. Bratt[1] *and S. Chantziara*[2]*, (1)Medway School of Pharmacy, Kent, United Kingdom of Great Britain and Northern Ireland, (2)Medway School of Pharmacy, Universities of Kent and Greenwich, Chatham, United Kingdom*

Background: Children with Autistic Spectrum Disorders (ASD's), present with inherently heterogeneous behavioural challenges & often concomitant physiological and psychiatric conditions. In general they require a higher need for medical support from a wide range of health care professionals throughout the course of their development than their neurotypical peers.

Objectives: No published data has currently been collected in the U.K. to show either, 1): How frequently children / young people with autism access all types of health care provision?, or 2): How satisfied their parents / carers are with the level of health-related support which their dependents with autism have received? The current study aimed to capture this information, in addition to testing what factors may shape the overall "healthcare experience".

Methods: Data were obtained by combined means of a paper & online, 25-item questionnaire distributed to parents of children (aged 0-18 years) with autism via 3 gatekeepers; Kent Autistic Trust, (KAT), Medway Autism Group and Information Centre, (MAGIC), & the National Autism Database U.K. The services surveyed were General Practitioners (GP's), Paediatricians, Child & Adolescent Mental Health Services, (CAMHS); Accident & Emergency & inpatient hospital admissions. Participants were asked if they had previously heard of Hospital passports; (HPs), (dossiers of integrated patient information), and if they considered whether HP's could hold potential utility for their child?

Results: Data were obtained from 214 completed questionnaires. Findings revealed that hospital services were used least, however parents were most satisfied with these acute care services, as well as with primary care provision from GP's. In contrast 60% of families were less than satisfied with mental health services provided by CAMHS. Parental satisfaction with hospital paediatrician services was higher among those who attended higher numbers of appointments than those accessing fewer consultations. Common qualitative themes raised concerns surrounding the level of ASD-specific knowledge among healthcare professionals, length of waiting times for referrals, & level of inter-specialism communication. Most participants, (80%) were unaware of the existence of hospital passports, however a large majority, (95%) considered them of potential benefit to their child / young person with autism.

Conclusions: Parental suggestions for healthcare improvements could potentially inform future practice to drive the need for ASD-related individualised care. Overall the profile of differences in parental satisfaction across healthcare services highlight that specific areas could be improved to be more adequately tailored to meet the holistic healthcare needs of children with autism.

198

185.198 The Effectiveness of Paid Facebook Advertising on Recruitment and Engagement in the Simons Foundation Powering Autism Research for Knowledge (SPARK) Research Initiative

V. J. Myers*, B. E. Robertson, A. Daniels, P. Feliciano and W. K. Chung, Simons Foundation, New York, NY*

Background:

Historically, participation in autism research has been low relative to other medical conditions. Past research indicates that only about 5-10% of individuals with autism have been in a clinical research study. Recruitment for autism research studies has been primarily through academic research centers which are limited to specific geographic areas. Social media platforms like Facebook, however, allow researchers to target their recruitment efforts more effectively and efficiently. There are an estimated 13 million Facebook users between the ages of 18 and 65+ with a defined interest in "autism awareness." Targeted Facebook advertising to these users for autism research may significantly enhance study recruitment and participation.

Objectives:

The primary aim of this study was to quantify the participants who joined SPARK through paid Facebook advertising from June through August

2017. A secondary aim was to measure the increase in followers via paid Facebook advertising and to evaluate the percentage increase in SPARK participation of individuals, families and fathers before and after the advertising period.

Methods:

A series of videos, graphic interchange formats (GIFs) and static images were created for use in paid Facebook advertisements. Engaging and inviting recruitment language was developed to accompany the digital assets. A tracking code was embedded within the HTML of the study website to measure the number of people who joined SPARK. The code was also used in targeting individuals who had initiated, but not completed registration. Characteristics of the targeted audiences included parents who had not completed registration, mothers with autism interests and married mothers with autism interests.

Results:

From June through August 2017, 2,899 individuals enrolled in SPARK through Facebook advertising. Advertisements to individuals who had initiated, but not completed registration were less effective and only 13 percent of new registrants came from this audience segment. The most successful target audience was married mothers with autism interests, which recruited 52 percent of the total. We saw a 73 percent increase in overall registration and a 20 percent increase in father registration during the study period. We saw a 61 percent increase in Facebook page likes during this time as well as increased engagement on the study's Facebook page.

Conclusions:

Facebook is an effective way to recruit participants for SPARK. Fathers are a difficult demographic to reach; but when targeting mothers on Facebook we see increased participation from fathers too. In summary, mothers are a more effective demographic to target through Facebook advertising to recruit participants for autism research.

199 **185.199** Autistic Identity (or Lack Thereof) in High School and Undergraduate Students

A. Riccio[1], *S. K. Kapp*[2], *J. Delos Santos*[3], *N. Tricarico*[4], *D. DeNigris*[5], *W. Pinkava*[4], *P. J. Brooks*[6] *and K. Gillespie-Lynch*[7], *(1)Department of Psychology, The Graduate Center, City University of New York (CUNY), New York, NY, (2)University of Exeter, Exeter, United Kingdom, (3)Hunter College, City University of New York, New York, NY, (4)College of Staten Island, City University of New York, Staten Island, NY, (5)Psychology & Counseling, Fairleigh Dickinson University, Madison, NJ, (6)Psychology, College of Staten Island, Staten Island, NY, (7)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY*

Background: Traditionally, autism has been researched by professionals who lack the lived experience of being autistic. As a result, disseminated information is often considered incomplete or inaccurate by autistic individuals. Researchers, lay persons, and autistic individuals alike may benefit from listening to views of autistic people, bridging gaps in understanding (Nicolaidis, 2012). Many autistic scholars and researchers view autism as a form of diversity rather than pathology (Pellicano & Stears, 2011). Identification with the neurodiversity movement, which encourages acceptance of neurological conditions, is prevalent among autistic individuals recruited online (Kapp et al., 2013). Online samples of autistic people demonstrate higher knowledge of and report lower stigma toward autism than non-autistic people (Gillespie-Lynch et al., 2017). We wished to examine if autistic young people recruited in person have similarly positive viewpoints about autism.

Objectives: We, four autistic and four non-autistic researchers, conducted a participatory study examining disability identity among autistic high school and college students recruited in person.

Methods: Autistic students attending high school (n=17) or college (n=22) in a metropolis completed structured interviews and assessments. High school students were recruited from a technology-based summer camp. Undergraduates were recruited from a mentorship program at a public university. All participants were asked to define autism and describe how autism can make someone stronger. High school students were also asked to "describe yourself to someone who doesn't know you". Similarly, undergraduates were asked to describe themselves using only six words/concepts; they also completed the *Reading the Mind in the Eyes* task (assessing ToM; Baron-Cohen et al., 2001). Autistic researchers involved in a broader participatory initiative encouraged us to focus on disability identity (stating that it is the most interesting research focus) and helped develop coding schemes and code.

Results: Irrespective of developmental level, few participants used strength-based terms when defining autism; many more cited challenges, especially social difficulties (Table 1). When prompted to do so, many high school and college students identified strengths they associated with autism (often citing perseverance). Undergraduates who could not define autism when asked had lower ToM scores (p=0.04). Participants who used strength-based language to define autism also used agentic words when describing themselves more generally (p=0.006). Only one participant self-identified using an autism-related term (Table 2).

Conclusions: As hypothesized, autistic high school and undergraduate students recruited in person were less likely to endorse acceptance of neurological differences than online samples (e.g., Gillespie-Lynch et al., 2017). While 36% of participants in prior online research described autism as a neutral difference, less than 10% of the autistic youth recruited in person in this study described autism as a neutral difference. In fact, over 50% of the autistic high school students could not describe autism at all. Students who highlighted strengths associated with autism described themselves agentically, suggesting that neurodiversity-aligned viewpoints are empowering. Findings align with conjectures by an autistic researcher that autism understanding increases with development (Jones et al., 2013) and suggest that autism research should be conducted in person and online simultaneously to maximize generalizability of findings.

200 **185.200** Mental Health Outcomes of a Parent Educations and Support Group for Parents of Children with Autism Spectrum Disorder

S. J. Cohen[1], *J. Hai*[2] *and M. Boyer*[1], *(1)University of California Santa Barbara, Santa Barbara, CA, (2)Education, UC Santa Barbara, Santa Barbara, CA*

Background: Parents of children with Autism Spectrum Disorder (ASD) report greater parenting stress, marital distress, and mental health symptomology than parents of typically developing children, as well as parents of children with other types of disabilities (Hayes & Watson, 2013; Karst & Van Hecke, 2012; Dabrowska & Pisula, 2010). Research suggests that social support, parenting self-efficacy, and coping styles moderate the association between autism and parenting stress (Dunn et al., 2001; Kuhn & Carter 2006). Parent support groups in general have been shown to raise awareness, decrease stress, and increase empowerment among participants (Soloman, M., Pistrang, N., Barker, C., 2001). Although many

support groups of varying structures exist for parents of children with ASD, little research exists on the mental health outcomes of these groups.
Objectives: The objective of the present study is to determine the impact of an 8-week Parent Education and Support group on the mental health and quality of life of parents of children with ASD.

Methods: Twenty parents will participate in this study. Families (i.e. parent dyads) will be randomly assigned to either the treatment or waitlist control condition. Thus, both groups will ultimately participate in the intervention. Before the treatment group begins the intervention, all parents will complete standardized self-report assessment measures of parenting stress, anxiety, depression, marital adjustment, and satisfaction with life. All parents will complete these measures again eight weeks later, after the treatment group has completed the intervention, and once again, eight weeks later, after the waitlist group has completed the intervention. The intervention will consist of an eight week curriculum that incorporates educational components within a discussion-based support group. The curriculum will include psycho-education about ASD, exploring strengths and challenges, discussion of resources for families with ASD (e.g. autism friendly hair dressers, dentists, community activities, etc.), navigating public education (e.g. advocacy in schools, Individualized Education Plans, Special Education, etc.), self-care, and coping skills. Parents will meet weekly with two graduate student clinicians, supervised by a licensed psychologist. Free childcare will be provided for all participating parents to allow participation of parents who might otherwise not be able to attend.

Results: This research study will be completed in March of 2018. Based on past research and current literature, we hypothesize that reported feelings of anxiety, depression, and stress will decrease, and that self-reported martial adjustment and satisfaction with life will increase for the parents who complete the eight week intervention, compared with the waitlist control group.

Conclusions: The results of this study will provide information regarding the effectiveness of this intervention for parents of children with ASD. The goal for these facilitated parent education and support groups is that parents will build social connections, increase their understanding of their child and how to support him/her, increase their awareness of resources available to them, and build effective coping strategies. As a result, we hope parents will experience less stress, anxiety, and depression, and experience greater marital satisfaction and quality of life.

201 **185.201** The Influence of Ethnicity, Family Problems, and Optimism on Services Received Among Latino and Non-Latino White Children with ASD

K. Lopez[1], *J. Reed*[2] *and S. Magaña*[3], *(1)Arizona State University, Phoenix, AZ, (2)Southwest Autism Research and Resource Center, Phoenix, AZ, (3)Steve Hicks School of Social Work, University of Texas at Austin, Austin, TX*

Background: There is increasing evidence of disparities in age of autism diagnosis and treatment access among Latino children with autism. In addition to language barriers, low socioeconomic status (SES) and limited access to health insurance, it is important to investigate additional factors that contribute to these disparities in the Latino population. Given the increased risk of family problems among families of children with ASD it is important to consider the influence of family problems on services received. Moreover, one's general orientation to adversity, including an optimistic perspective may mediate the influence of family problems on the amount of services received. Given that previous research has found Latino mothers to report less family problems and to have more optimistic perspectives than white families when faced with adversities we sought to explore the relationship among family problems, optimism, and services received among Latino and non-Latino White parents raising children with autism.
Objectives: We investigated a mediation model for services received among Latina and non-Latina White mothers. First, we aimed to identify whether optimism mediated the relationship between family problems and services received. Second, we aimed to explore the role of ethnicity as a moderator within the proposed mediation model.

Methods: Forty-five Latino caregivers and 56 non-Latino White caregivers were administered a questionnaire on their experiences with their child's diagnosis and service use. Children were between 3 and 21 years of age (μ=9.6; SD=4.5) at the time of the study. A global measure of *Optimism* was based on the Life Orientation Test. *Family Problems* was measured by the parent and family problems subscale in the Questionnaire on Resources and Stress. *Child behavior problems* was measured using the Scales of Independent Behavior-Revised. *Services received* was based on responses to 7 items pertaining to whether children had ever received a given service.

Bivariate correlations were conducted for all variables in the study. A mediation model was produced using Baron and Kenny's (1989) four step model to mediation. The independent variable was family problems. The dependent variable was the number of services received. The proposed mediator was mother's optimism. Following, we included ethnicity as a moderator in the mediation model using the PROCESS macro in SPSS 24. We expected ethnicity to moderate the relationship between family problems and optimism.

Results: The results for the mediation analyses indicated that optimism did mediate the relationship between family problems and services received. The regressions indicated that more family problems predicted more services received. Fewer family problems predicted greater optimism. Family problems was no longer a significant predictor of services received after controlling for the mediator, optimism. The results for the moderated mediation model indicated that ethnicity was not significant.

Conclusions: Analyses indicate that the number of family problems perceived by mothers contributes to the number of services children with ASD receive, as did mother's global optimism. Understanding the influence of these factors on services received has implications for the development of interventions addressing services for children with ASD and their families.

Poster Session
186 - Medical and Psychiatric Comorbidity
11:30 AM - 1:30 PM - Hall Grote Zaal

202 **186.202** Anxiety and Depression from Adolescence to Old Age in Autism Spectrum Disorder

M. Uljarevic[1,2,3], *D. Hedley*[4], *K. R. Foley*[5], *I. Magiati*[6], *R. Y. Cai*[4], *C. Dissanayake*[4], *A. L. Richdale*[4] *and J. Trollor*[5], *(1)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, CA, (3)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (4)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (5)The University of New South Wales, UNSW Sydney, Australia, (6)Psychology, National University of Singapore, Singapore, Singapore*

Background: Most research on anxiety and depression in autism spectrum disorder (ASD) has focused on children and adolescents. In the general population, anxiety and depression show distinct trajectories across the lifespan with increasing negative impact on functioning over time. As ASD is a lifelong condition, it is important to understand the rates, presentation, and impact of anxiety and depression across different developmental periods, especially from adolescence into young and middle adulthood and beyond.

Objectives: The first aim of the current study was to examine age trends in anxious and depressive symptoms from older adolescence to middle and older adulthood, in a large, cross-sectional sample of adolescents and adults with ASD. The second aim was to examine the association between anxious and depressive symptomatology and other individual characteristics, including gender and ASD symptom severity, as well as socio-economic factors relating to education level and current employment status.

Methods: 255 adolescents and adults with ASD (151 males, 59.2%; M_{age}= 33.52 years, *SD*= 14.98, range: 14.29-80.16 years) completed the Abridged Version of the Autism-Spectrum Quotient (AQ-28), DSM-5 Dimensional Anxiety Scale (DSM-5 DAS) and the Patient Health Questionnaire-9 (PHQ-9) to assess self-reported ASD, anxiety and depression symptoms respectively. Participants were recruited through three Australian studies: the Longitudinal Study of Australian School Leavers with Autism, the Australian Longitudinal Study of Adults with Autism, and the Dandelion Program.

Results: More than one-third of participants reported clinically elevated anxiety (38.4%) or depression (38%). There were no differences between adolescents (15-19 years), young adults (20-39 years), middle-age (40-64 years), and old age (65+ years) adults in anxiety raw scores (F= 1.50, p= .21, ηp^2 = .018) but there were statistically significant differences in depression (F= 2.77, p= .042, ηp^2= .032), with post-hoc comparison showing that individuals in the middle-aged group had significantly higher depression scores than individuals in the adolescent age group (p= .04, *Cohen's d*= .45, BCa 95CI [-5.89, -.08]). There were no group differences in the proportion of individuals who scored above or below the clinical cut-off scores for depression, χ^2= 5.40, p= .14, *Phi*= .145, or anxiety, χ^2= 3.01, p= .39, *Phi*= .109 Linear regression models were used to explore predictors of anxiety and depression. For anxiety, the overall model explained 10.7% of variance, F = 15.05, p < .001, with female gender (β= .16, t= 2.56, p= .011) and higher AQ total score (β= .23, t= 3.68, p < .001) being unique significant independent predictors of higher anxiety symptom severity. For depressive symptomatology, the regression model explained a total of 15.5% of the variance, F = 11.51, p < .001, with female gender (β= .21, t= 3.33, p= .001) and higher AQ total score (β= .27, t= 4.04, p < .001) also independently predicting depression.

Conclusions: Findings from our study provide evidence that both anxiety and depression are highly prevalent across the lifespan in individuals with ASD and emphasise the need to provide a timely and accurate assessment of these co-occurring symptoms in young, middle and older adulthood.

203 **186.203** Association between Sleep Problems and Aggressive Behavior, Attention Problems, and Internalizing Behaviors Using Baseline and Follow-up Data in the Autism Speaks-Autism Treatment Network Registry

A. M. Shui[1,2], *T. Katz*[3], *B. A. Malow*[4] *and M. O. Mazurek*[5], *(1)University of California San Francisco, San Francisco, CA, (2)Biostatistics Center, Massachusetts General Hospital, Boston, MA, (3)Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO, (4)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN, (5)University of Virginia, Charlottesville, VA*

Background: Sleep difficulties in children with Autism Spectrum Disorder (ASD) have been well established, and studies indicate that 50 to 80% of children with ASD have sleep problems. Aggression has been reported in previous literature as associated with sleep problems among children with ASD in cross-sectional studies. Sleep problems are also associated with increased internalizing and externalizing behavior and hyperactivity. Establishing an association between daytime behaviors and sleep problems over time may help with treatment and prevention of both sleep problems and daytime behaviors.

Objectives: To determine if change in sleep problems is associated with change in daytime behaviors from baseline to first 1-year follow-up among young children with ASD.

Methods: In a sample of children under 6 years-old in the Autism Speaks-Autism Treatment Network (ATN) registry with both baseline and first follow-up Child Behavior Checklist (CBCL) scores available, change scores were calculated from age- and sex-adjusted z-scores by subtracting z-score at baseline (visit 1) from z-score at first follow-up (visit 2). Change scores were calculated for the CBCL syndrome scales: Sleep Problems, Aggressive Behavior, Attention Problems, Emotionally Reactive, Anxious/Depressed, Somatic Complaints, and Withdrawn. The associations between the sleep problems change score and each of the daytime behavior change scores were assessed using adjusted generalized linear models (GLM), controlling for baseline characteristics including demographics and DSM-IV diagnosis. The multiple imputation method was used to address missing data in each model, and a Holm-Bonferroni step-down procedure was applied to the six daytime behaviors to address multiple comparisons. Each adjusted p-value was compared to a significance threshold of 0.05, and nominal p-values prior to the adjustment were also reported.

Results: Of the 3,722 children under age 6 in the ATN registry, 457 had both baseline and first follow-up CBCL scores available. Mean age at baseline CBCL assessment was 3.5 years (SD 0.82), and most children were male (80.7%), non-Hispanic (93.1%), white (83.8%), had caregivers who completed at least some college (82.7%), and had a DSM-IV diagnosis of autistic disorder (68.2%). Adjusting for baseline characteristics and multiple comparisons, aggressive behavior and attention problems change scores were significantly associated with sleep problems change scores. On average, for each unit increase in aggressive behavior change score, sleep problems change score increased by 0.352 ($p<0.001$); and for each unit increase in attention problems change score, sleep problems change score increased by 0.234 ($p<0.001$). By contrast, internalizing behaviors were not correlated with increased difficulties with sleep.

Conclusions: Among young children with ASD, worsening aggressive behavior and attention problems were correlated with worsening sleep problems from baseline to first follow-up. These data highlight the importance of evaluating young children's sleep when aggressive behavior and attention problems are present. Addressing aggressive behavior and attention problems may help with treatment and prevention of sleep problems, and addressing sleep problems may also help with treatment and prevention of aggressive behavior and attention problems. Future research is needed to better understand the association between sleep and aggression/attention to determine if improvements in aggression/attention lead to improvement in sleep or vice versa.

204 **186.204** Associations between Sleep Structure and EEG with Daytime Functioning in ASD

R. Godbout, *Psychiatry, Université de Montréal, Montréal, QC, Canada*

Background: Sleep significantly interacts with daytime functioning. This will be illustrated by a series of studies in school-age children and young adults with ASD by describing the associations between, on one hand, sleep structure and EEG and, on the other hand, clinical measures, cognitive performance, and sensori-motor performance.
Objectives: The objectives of these studies were to elucidate the relationships between sleep structure and daytime functioning using gold stand sleep assessment methods.

Methods: Groups of 11-14 ASD children (mean age 10.3, *SD* = 2.2, range: 6–13) and 15-18 ASD adults (mean age 21.7, *SD* = 3.5, range: 16-27) were diagnosed with AID-R and ADOS. To identify relationships specific to autism, we recruited participants with ASD free from comorbidities including Intellectual Disability, epilepsy, and other psychiatric diagnoses. Results were compared to 13-15 neurotypical (NT) children (mean age = 10.2, *SD* = 2.0, range 7–12) and 14-17 NT adults (mean age 21.7, *SD* = 3.5, range: 16-27). All participants were recorded in a sleep laboratory using polysomnography (PSG) for two consecutive nights; only sleep/EEG data from night 2 were used. Behavioral scales were filled during the previous 2 weeks. Neuropsychological tests (adults only) were administered in the mornings following nights 1 and 2.

IQ measures were generally comparable between ASD and NT groups. Both age groups of participants with ASD showed more internalizing problem behaviors than the NT groups. Neuropsychological performance was lower in adult participants with ASD, particularly in tasks at least partly based on motor output.

Results: Sleep structure in participants with ASD differed from that of NT participants in both age groups, with long sleep latencies, more light nonREM (N1) sleep, and low levels of deep nonREM (N3) sleep; measures of REM sleep were comparable. Light nonREM sleep correlated negatively with IQ scores (Wechsler's and Raven's) in both groups of children. No significant correlations were found in adults but light nonREM sleep correlated negatively with reaction times on selective attention and procedural learning tasks. Deep nonREM (N3) sleep was negatively correlated with internalizing problem behaviors in children while REM sleep showed this association in adults. Deep nonREM (N3) sleep was negatively correlated with reciprocal social interactions core (ADOS) and positively correlated with repetitive behaviors (ADI-R).

EEG sleep spindles were less frequent in children (frontal electrodes) and adults (central electrodes) with ASD when compared to NT participants. Fewer sleep spindles were associated with (1) more trials required for learning a sensori-motor procedural task (rotary pursuit) and (2) higher IQ scores. Slow (delta) EEG activity was (1) lower in adult participants with ASD, (2) uncorrelated with IQ, and (3) negatively correlated with sensori-motor performance.

Conclusions: Signs of poor sleep are associated with impaired daytime performance in ASD as well as NT groups of participants, regardless of age. Patterns of relationships, however, differ according to age and clinical status. These results illustrate the atypical development of cortical afferent and efferent systems in ASD. They also raise the possibility that these systems act differently to regulate behavior in different age and clinical groups.

205 **186.205** Autism and Eating Disorders in Women: A Function of Age

C. M. Brown[1], M. Fuller-Tyszkiewicz[2], I. Krug[3] and ***M. A. Stokes****[4], (1)School of Psychology, Deakin University, Melbourne, Australia, (2)Deakin University, Melbourne, Australia, (3)University of Melbourne, Melbourne, Australia, (4)Deakin University, Burwood, Australia*

Background: Some evidence suggests that eating disorders (EDs) and Autism Spectrum Disorders (ASD) may be related in women, though how these comorbidities differ across diagnosis and age is not well established. It was hypothesised that a) the relationship between ASD and anorexia nervosa would be stronger than other types of EDs, and b) the strength of the relationship between ASD and all EDs would decrease as age increased.
Objectives: To understand the nature of the relationship between ASD and eating disorders in adult women.

Methods: We recruited 897 women between the age of 18 and 68 (*M*=32.06, *SD*=9.41) online through specialist support services and social media. The sample contained *N*=551 typically developing women, *N*=151 with ASD, and *N*=195 with EDs. Self-declared diagnoses were confirmed by use of the Autism-Spectrum Quotient (AQ), and the Eating Attitudes Test (EAT-26).

Results: Data were stratified into two discreet age brackets. For those aged 18-34 years, Chi-square analysis found 45.5% of women with ASD also displayed high ED traits ($\chi^2_{(1)}$=20.27, *p*<.001, *N*=77), while 31.5% of women with an ED also displayed high ASD traits ($\chi^2_{(1)}$=9.99 *p*<.005, *N*=111). Multiple regression revealed that EAT-26 subscales Dieting, and Oral Control significantly predicted AQ scores, while Bulimia & Food Preoccupation did not. For the group aged 35+ years, Chi-square analysis found that women with and without ASD had similar levels of ED traits ($\chi^2_{(1)}$=3.75, *p*=.05, *N*=45, 31.1%), while women with and without an ED differed substantially in the proportion with high ASD traits ($\chi^2_{(1)}$=0.00, *p*=.964, *N*=37, 24.3%). Multiple regression revealed Dieting was the only significant predictor of AQ scores.

Conclusions: Over the age of 35, the relationship between ASD and EDs was non-significant, which is likely to be reflective of the younger age at which EDs are more prevalent (Ackard, Richter, Frisch, Mangham & Cronemeyer, 2013). The study was limited in that it only had the capacity to examine current ED traits, and not historical diagnoses of EDs, though this is an area in which further investigation is warranted. There also appears to be variation in the type of ED related to ASD among women, with anorexic symptomology having the greatest predictive power for ASD traits, which is consistent with existing literature (Huke, Turk, Saeidi, Kent, & Morgan, 2013). This study highlights the necessity for greater understanding of female specific ASD presentation.

206 **186.206** Autism Spectrum Disorder in an Unselected Cohort of Children with Neurofibromatosis Type 1 (NF1)

S. Eijk, ***S. E. Mous****, G. C. Dieleman, B. Dierckx, A. B. Rietman, P. F. de Nijs, R. van Minkelen, C. E. Catsman-Berrevoets, R. Oostenbrink and J. S. Legerstee, Erasmus MC-Sophia Children's Hospital, Rotterdam, Netherlands*

Background: Recently, studies have started to focus on the prevalence and profile of Autism Spectrum Disorders (ASD) in children with neurofibromatosis type 1 (NF1), and prevalence rates of ASD symptoms ranging between 13-30% have been reported. However, these estimates are often based on screening instruments and pre-selected samples of children with NF1 with an initial suspicion of autism spectrum problems, and are most likely not representative for the general pediatric NF1 population.
Objectives: We aimed to examine the prevalence of ASD in an unselected sample of children with NF1 without a presumption of ASD. Additionally, we assessed the predictive value of a screening- and clinical observational instrument in relation to clinical DSM-IV ASD diagnosis in a pediatric NF1 population, and we examined possible correlates.

Methods: In 128 children, aged 2-10, the Autism Diagnostic Observation Schedule (ADOS; a clinical observational instrument for ASD assessment) was administered, and 103 parents also completed the Social Responsiveness Scale (SRS; a screening instrument for autism symptoms). All children were clinically assessed by a child psychiatrist.

Results: A prevalence rate for clinical ASD of 10.9% was found. The positive predictive value in relation to the DSM-IV ASD diagnosis was highest when the screening- and observational instrument were combined. An ASD diagnosis was associated with gender and age; more boys were diagnosed with ASD and the group of children with an ASD diagnosis was older.

Conclusions: This ASD prevalence rate is clearly higher than in the general population, but lower than has been previously reported in NF1 studies using pre-selected samples of children with a presumption of ASD. Furthermore, our results highlight the importance of using both the ADOS and SRS for the identification of ASD in children with NF1.

207 **186.207** Characteristics of Autism Spectrum Disorder in Russell-Silver Syndrome

***C. Lane**, E. Milne and M. Freeth, The University of Sheffield, Sheffield, United Kingdom*

Background:

Russell-Silver syndrome (RSS) is a rare condition associated with slowed growth both prenatally and postnatally. It is estimated that approximately 60% of individuals with a clinical diagnosis of RSS have an identifiable molecular cause. The most common molecular abnormalities are loss of methylation on chromosome 11p15 (observed in 30 – 60% of patients with a clinical diagnosis) and maternal uniparental disomy for chromosome 7 (MUPD7) (observed in 5 – 10% of patients with a clinical diagnosis). Previous research has indicated that autism spectrum disorder (ASD) may be common in individuals with RSS and particularly in those with RSS MUPD7. However, to date, the prevalence of ASD in RSS has not been systematically investigated using standardised assessments.

Objectives:

The aim of this study was to identify the prevalence of ASD in RSS 11P15 and RSS MUPD7, using a quantitative measure of ASD symptomatology - the Social Responsiveness Scale, second edition (SRS-2).

Methods:

The SRS-2 is a 65-item questionnaire, designed to assess severity of ASD symptomatology and is consistent with the DSM-5 criteria for ASD. The parent/caregiver of each participant completed the SRS-2 for 37 individuals with a diagnosis of RSS 11P15 (mean age = 7.71 years, SD = 4.47) and 23 individuals with a diagnosis of RSS MUPD7 (mean age = 9.17 years, SD = 6.46).

Results:

As assessed by the SRS-2, 38% of participants with RSS 11P15 and 43% of participants with RSS MUPD7 scored above clinical cut-off for ASD (total T-score ≥ 60). The findings indicated that individuals with RSS 11P15 and individuals with RSS MUPD7 displayed similar severity of difficulty with social communication impairment. However, individuals with RSS MUPD7 had greater difficulty with restricted interests and repetitive behaviours, compared to individuals with RSS 11P15.

Conclusions:

Overall, the findings indicate that individuals with RSS 11P15 and individuals with RSS MUPD7 display increased prevalence of behavioural symptomatology associated with ASD. In addition, individuals with RSS MUPD7 display particular difficulty with restricted interests and repetitive behaviours.

208 **186.208** Co-Occurring Psychopathology in Children with Autism Spectrum Disorder of Normal-Range Intelligence

***E. L. Palluotto**[1], W. Mandy[2] and D. H. Skuse[3], (1)Oxford Health NHS, Buckinghamshire, United Kingdom, (2)University College London, London, United Kingdom of Great Britain and Northern Ireland, (3)Behavioural and Brain Sciences Unit, Population Policy and Practice Programme, UCL Great Ormond Street Institute of Child Health, University College London, London, United Kingdom*

Background: Increasing evidence indicates that children with Autism Spectrum Disorder (ASD) experience high rates of co-occurring psychopathology, particularly Attention-Deficit-Hyperactivity-Disorder (ADHD), Anxiety and Depression (Salazar et al., 2015; Simonoff et al., 2008). Affected children with co-occurring psychopathology have poorer outcomes, including an increased risk of hospitalisation. In some respects, the reported characteristics of ASD comorbidity resemble equivalent conditions when those are found in typically developing children. For instance, there is a greater prevalence of internalising psychopathology in females and externalising psychopathology in males. Former studies of comorbidity that have evaluated risk for psychopathology have focused largely on children with intellectual disability, but >85% of ASD is nowadays diagnosed in those with normal-range IQ.

Objectives: This study aimed to identify patterns of psychiatric comorbidity among newly diagnosed ASD children with normal or high IQ, by means of a standardized parental interview, the Development and Wellbeing Assessment (DAWBA) (Goodman et al., 2011). Psychiatric disorders included Panic Disorder, Agoraphobia, PTSD, Eating Disorder, OCD, Depression, Tic Disorder, Separation Anxiety, Social Phobia, GAD, Specific Phobia and ADHD**.** Previous methodological limitations have been minimised by using standardized assessment tools that identified indices of severity, in terms of both ASD and comorbid conditions. Because UK national psychiatric comorbidity data have also been collected by the DAWBA (2016-7), comparisons with general population prevalence and patterns of comorbidity in a non-ASD sample were also possible.

Methods: 78 consecutive referrals (*N*=78; 44 males, 34 females, 5-17 years, *M*age=10.45 years, *SD*=3.5) were recruited from a specialist ASD assessment service. All had normal-high range intelligence (*M*FSIQ=92, *SD*=17) and a clinical diagnosis of ASD (DSM-5 criteria) made based on structured parental interview (3di) and Autism Diagnostic Observation Schedule (ADOS) scores. Parent DAWBA data were available in all cases, plus school reports.

Results: Sixty-five percent met criteria for at least one comorbid disorder, including ADHD (39%) and Specific Phobias (22%). Logistic regression revealed ADHD traits were more common in ASD males than females (OR 3.554 [95% CI 1.245-10.143]). There was no gender difference in the prevalence of comorbid Anxiety or Depression (p>0.05). Depressive traits were more prevalent in older children (OR 1.378 [95% CI 1.046-1.815]). Social Phobia was associated with ASD severity (OR 1.471 [95% CI 1.013-1.983]).

Conclusions: Comorbid psychiatric traits are much more common among children with high-functioning ASD than in typically developing populations. Unless structured screening for comorbidity is undertaken as a routine clinical procedure when assessing children with suspected ASD of normal range intelligence, concurrent disorders may be overlooked, and hence untreated.

209 **186.209** Common and ASD-Distinct Anxiety Presentations and Their Association with Individual Characteristics in a Large Pooled Database of Young People with ASD

B. Y. Lau[1], R. Leong[1], M. Uljarevic[2,3], A. Ozsivadjian[4], J. W. Lerh[1], M. J. Hollocks[5,6], J. Rodgers[7], H. McConachie[8], M. South[9], A. V. Van Hecke[10], A. Y. Hardan[11], R. Libove[11,12], S. R. Leekam[13], E. Simonoff[14] and ***I. Magiati***[1]*, (1)Psychology, National University of Singapore, Singapore, Singapore, (2)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (3)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (4)St. Thomas Hospital, Evelina London Children's Hospital, london, UNITED KINGDOM, (5)King's College London, Cambridge, UNITED KINGDOM, (6)Department of Clinical Psychology, University of East Anglia, Norwich, United Kingdom, (7)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (8)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (9)Psychology & Neuroscience, Brigham Young University, Provo, UT, (10)Psychology, Marquette University, Milwaukee, WI, (11)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (12)Medicine (Parker Lab), Stanford University, Stanford, CA, (13)School of Psychology, Cardiff University, Cardiff, NSW, United Kingdom, (14)King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom*

Background: Clinically elevated anxiety symptomatology and disorders occur in high rates in young people with ASD. Anxiety symptoms in young people with ASD can be consistent with those found in DSM-5 (also termed as “common” anxieties), while a substantial number may also present with anxiety symptoms that are qualitatively different and more distinct to ASD (“ASD-distinct”).
Objectives: Few studies have systematically examined the phenomenology of anxiety in ASD and only one study to date has explored the associations between different individual characteristics with common and ASD-distinct anxiety presentations. Most current anxiety measurement tools are designed for individuals without ASD and thus, have been inadequate in capturing possible qualitative differences of anxiety in ASD. This research study aims to extend on limited existing literature that examines emerging themes of anxiety symptomatology in ASD, as well as investigating possible associations between individual characteristics and presentations of common and ASD-distinct anxieties.

Methods: Participants were 870 6-18 years old young people with ASD from UK (n=465), Singapore (n=241), and USA (n=164) from an international multi-site pooled database. Caregivers completed the Spence Children's Anxiety Scale – Parent Version (SCAS-P). Open-ended responses to item 39 (“Is there anything else your child is afraid of?”) were coded, and thematically and quantitatively analyzed to investigate (i) differential presentations of anxiety in ASD and (ii) associations between age, gender, cognitive functioning and autism symptom severity and ASD-distinct anxieties.

Results: Nearly half (47.6%) of the 545 responses obtained from 287 participants in the open-ended optional item 39 were found to be ASD-distinct anxieties. Of those, 54% were sensory, 28.2% were specific unusual phobias; 16% were fears about change/ unpredictability/ routine disruption; and 2.1% were relating to ASD specific social demands. Individuals of younger ages, lower overall cognitive functioning, and higher autism symptom severity tended to present with more ASD-distinct anxieties as compared to common anxieties, while age and autism severity were found to be significant independent predictors of reported ASD-distinct anxieties in subsequent regression analyses.

Conclusions: The results appear to support a profile of both common and ASD-distinct anxiety phenomenology amongst young people with ASD. Future clinical assessments or measures of anxiety should aim to routinely include questions, probes and clarifications to enquire about, and disentangle, both common and ASD-distinct anxieties.

210 **186.210** Comorbid Down Syndrome and ASD: Differential Social Affect in ASD Symptoms

T. Hamner[1,2]*, D. L. Robins[3], D. Fidler[4], S. Hepburn[4], N. R. Lee[2] and C. Robinson Rosenberg[5], (1)AJ Drexel Autism Institute, Philadelphia, PA, (2)Department of Psychology, Drexel University, Philadelphia, PA, (3)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (4)Colorado State University, Fort Collins, CO, (5)University of Colorado / JFK Partners, Aurora, CO*

Background: Little is known about the ASD symptom profile of children with comorbid Down syndrome and ASD (DS+ASD). Whereas previous literature suggests limited social impairments in individuals with DS-only (Fidler, 2005), recent research demonstrates an estimated 20% of the DS population has ASD (DiGuiseppi et al., 2010). The limited research available suggests children with DS+ASD have fewer social impairments than in ASD but similar communication impairments; however, social functioning has largely been assessed using parent-report (Warner et al., 2017) or in very small samples (*n*=3; Hepburn et al., 2008). Elucidating differences in ASD symptoms for those with ASD and a comorbid genetic syndrome can further our understanding of the nature and etiology of ASD in these children. Identifying ASD symptom profiles of children with comorbid DS+ASD early in development is critical to informing early identification and intervention.
Objectives: The goal of this study is to assess ASD symptom profiles within and between clinical samples of children with ASD, DS, and DS+ASD.

Methods: Participants included 93 children (59 males; Mean age= 60.43 months) with ASD (n=43), DS (n=38), and DS+ASD (n=12). Data were compiled from a larger study completed at the University of Colorado School of Medicine/Colorado State University (DiGuiseppi et al., 2010) and from the National Database for Autism Research. ASD symptoms were assessed using the ADOS Module 1 and scores were converted to severity scores using the algorithm described by Gotham and colleagues (2007). A 3x2 mixed-model ANOVA with one between subjects factor (diagnostic group: DS, ASD, DS+ASD) and one within subjects factor (ADOS scale: social-affect (SA) and restricted, repetitive behaviors (RRBs)) was completed to examine if SA and RRBs are differentially impacted in the DS+ASD group compared to the other two groups.

Results: A significant group-by-scale interaction was revealed (F [2, 86] = 5.33, $p < 0.001$ using a Greenhouse-Geisser adjustment); each group presented with unique profiles. Specifically, the DS+ASD group had a profile unlike either the DS or ASD in isolation groups. Compared to those with ASD, SA in DS+ASD was significantly less impaired; in contrast, RRBs were similar across ASD and DS+ASD. Compared to those with DS, SA and RRBs were significantly more impaired in the DS+ASD group.

Conclusions: Results suggest ASD symptom profiles for children with DS+ASD are not similar to those with either ASD or DS in isolation. Specifically, whereas the DS+ASD group presents with RRBs similar to those with ASD, SA is less impacted and may act as a protective factor within this group. Given prior research suggesting social abilities are a relative strength for those with DS, investigation of the contribution of reciprocal social interaction and communication to overall social affect within this group is important. Discrepancies within social affect, characteristic to

ASD, have important implications for both early identification and intervention. As early intervention has been shown to alter developmental trajectories and improve lifetime outcomes for children with ASD (Orinstein et al., 2014), it will be important to investigate whether these interventions will have similar benefits for those with DS+ASD.

211 **186.211** Cumulative Sleep Loss and Challenging Behaviors during Treatment for Children with Autism

E. A. Abel[1]*, A. J. Schwichtenberg*[1]*, S. L. Christ*[2] *and M. Brodhead*[3]*, (1)Purdue University, West Lafayette, IN, (2)Human Development & Family Studies, Purdue University, West Lafayette, IN, (3)Michigan State University, East Lansing, MI*

Background: Sleep problems are common in children with autism spectrum disorder (ASD) and can exacerbate challenging daytime behaviors and ASD symptoms. In early childhood, individuals with ASD often receive intensive behavioral interventions using a center-based model, although no published studies have addressed how sleep may influence challenging behaviors in this developmental context.
Objectives: Following models of sleep debt, the present study aimed to address the potential cumulative effects of sleep loss on challenging behaviors occurring in the context of treatment. Specifically, we explored the following research question: On sequential preceding nights in which a child has poor sleep, does he/she exhibit more challenging behaviors the following day? We hypothesized that children with more cumulative sleep loss and/or fragmentation (averaged across all sequential preceding nights of sleep) would exhibit more challenging behaviors on the subsequent day.

Methods: This study included 42 children with ASD (2-10 years). All children had a medical ASD diagnosis and attended a behavioral intervention center five days a week. Sleep was assessed for five, consecutive 24-hour periods (Sunday–Thursday) using an actigraph and a coupled parent-report sleep diary. Daytime behaviors were recorded during the child's treatment hours by his/her behavioral clinician (Monday–Friday)—in conjunction with the sleep assessment schedule. Daytime behaviors included repetitive behaviors, aggression, negative affect, and self-injury. Partial–interval recording was implemented in five–minute intervals for the entirety of the treatment day, and clinicians indicated whether each behavior was observed within each interval.

Generalized linear mixed effects models were used to assess relations between sequential nights of sleep and each target behavior. Sequential measurements of sleep were calculated by maintaining a running average of sleep estimates over the course of the week. For example, Wednesday's behavior would be predicted by the average of sleep for Sunday, Monday, and Tuesday. Terms for level of functioning, caregiver education, sex, and age were included in each model. Total sleep time (TST) and wake after sleep onset (WASO) were included in separate models as predictors of each challenging behavior.

Results: Overall, children who slept less at night engaged in more repetitive behaviors and more negative affect during the day (Table 1). For every three hours of sleep missed (on average) over the previous consecutive nights, children engaged in ~one additional repetitive behavior and ~.50 negative affect expressions per hour. Additionally, for every three hours of WASO, children exhibited ~one additional negative affect expression per hour.

Conclusions: Our findings suggest that, in isolation, one night of poor sleep may not be consequential for a child's challenging behaviors during treatment. Rather, consistent with the theories of sleep debt, unrecovered sleep loss across multiple preceding nights was associated with greater risk for challenging daytime behaviors. Findings from the present study highlight sleep as one potential mechanism to reduce challenging behaviors—particularly when children exhibit extended patterns of maladaptive sleep behaviors.

212 **186.212** Decreased Satisfaction in Peer Relationships Is Strongly Associated with Depression in Children with High ASD Traits: A Population-Based Cross-Sectional Study in Japan

M. Takahashi[1]*, M. Adachi*[1]*, S. Yasuda*[2] *and K. Nakamura*[3]*, (1)Research Center for Child Mental Development, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (2)Research Center for Child Mental Development Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (3)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan*

Background: High rates of depression have been reported among children with autism spectrum disorder (ASD); however the relationship between depression and ASD traits observed in a community-based children sample has not yet been studied. In addition, the association between health-related quality of life (HRQOL) and depression in children with high ASD traits in a general population has not been evaluated, although that between HRQOL and depression has been reported in children with ASD in a clinical setting.
Objectives: This study aimed to examine how ASD traits are associated with depression in children using a population-based community sample. Moreover, we investigated how HRQOL is associated with depression in children with high ASD traits.

Methods: We conducted a survey among all children above grade 4 who attended national and public primary or junior high schools and their primary caregivers in September 2016. Of 8518 questionnaires, we received 7147 valid responses (83.9%). We evaluated ASD traits in children using a parental reported questionnaire, Autism Spectrum Screening Questionnaire (ASSQ). The Depression Self-Rating Scale for Children (DSRS-C) and Pediatric Quality of Life Inventory™ (PedsQL™), both self-reported questionnaires, were used for evaluating depression and HRQOL, respectively.

Results: The results of multiple regression analysis for all children revealed that ASSQ score and all subscale scores of PedsQL™ and other demographic factors were significantly associated with DSRS-C score, indicating that high ASD traits were associated with more severe depression even in a community sample of children. Moreover, we conducted multiple regression analyses by categorizing children into two groups based on ASSQ scores (score ≥ 19 or not) in order to examine how ASD traits influence on the relationship HRQOL and depression. Consequently, only emotional and social functioning were significantly associated with depression in the high ASD trait group, although all four PedsQL™ subscale scores were significantly associated with depression in the low ASD trait group. However, the relationship between social functioning score and depression was stronger in the high ASD trait group ($\beta = -0.324$, $p < 0.001$) than in the low ASD trait group ($\beta = -0.177$, $p < 0.001$). The association between emotional functioning and depression was comparable between the high and low ASD trait groups ($\beta = -0.347$, $p < 0.001$ vs. $\beta = -0.391$, $p < 0.001$). These results indicated that decreased satisfaction in peer relationships was more strongly associated with depression in children with high ASD traits than in those with low ASD traits. Furthermore, Analysis of variance for the PedsQL™ subscale scores revealed that all subscale scores were higher in the high ASD trait group than in the low ASD trait group, and the largest effect size was observed in the difference of the social functioning score between groups ($d = 0.82$).

Conclusions: Decreased satisfaction in peer relationships is more strongly associated with more severe depression in children with high ASD traits

than in those with low ASD traits. This result suggests that intervention in the quality of peer relationships among children with high ASD traits is essential to prevent depression.

213 **186.213** Depression in Children with Autism Spectrum Disorders: Measurement and Associations.

S. Brice[1]*, E. Honey*[2]*, J. R. Parr*[3]*, S. Wigham*[1] *and J. Rodgers*[3]*, (1)Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Northumberland, Tyne & Wear NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom, (3)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom*

Background: Children with autism spectrum disorders (ASD) are acknowledged to have an elevated risk of developing depression compared with their typically developing peers. Despite this, depression is poorly understood and often underdiagnosed in this group. The lack of reliable and valid measures of depression in this population are likely a factor in this. There is emerging evidence of a relationship between depression and a variety of psychological constructs, including traits of ASD although the mechanisms underlying these relationships is as yet unclear.
Objectives: This multi-phased study aimed to further the conceptual understanding of depression in children with ASD. Firstly we aimed to explore the latent factor structure of a well-used measure of childhood depression in a sample of children with ASD. Following this, we aimed to assess the psychometric properties of the measure as well as its acceptability to parents of children with ASD. Finally, the study aimed to explore the direct and indirect relationships between sensory hyposensitivity, restricted and repetitive behaviours and depression in children with ASD.

Methods: Participants were parents of 127 children with ASD without comorbid intellectual disability and 11 parents attended the focus groups for consultation regarding the depression measure. Participants were recruited from two autism research databases in the United Kingdom. Polychoric exploratory factor analysis was used to explore the factor structure of the Children's Depression Inventory (2nd Edition) in a sample of parents of children with ASD. Participants from both datasets were included as they were found not to differ significantly from one another across a range of key characteristics. The psychometric properties of the emergent factor structure were assessed and the model fit was tested by confirmatory factor analysis using structural equational modelling. Hayes (2009) mediation models were then used to explore the direct and indirect relationships between depression and traits of ASD.

Results: The results supported a unifactorial depression scale, with the removal of three of the original seventeen items. This scale evidenced promising reliability and validation however further adaptation is advised based on consultation with parents and poor model fit highlighted during confirmatory factor analysis. Mediation analyses highlighted significant and previously unreported direct and indirect relationships between sensory hyposensitivity, restricted and repetitive behaviours and depression.

Conclusions: These findings constitute the first steps in the creation of a psychometrically robust measure of depression in children with ASD. This can have clinical utility in terms of improved screening for depression in a population whereby it is currently often missed. The potential roles of sensory processing and restricted and repetitive behaviours in the prediction and maintenance of depression offer new avenues for future research and clinical intervention.

214 **186.214** Disparities in Care: An Investigation of Children with Autism Spectrum Disorder and Appendicitis

E. Friedlaender[1]*, H. Griffis*[2,3]*, J. Faerber*[4]*, W. Quarshie*[5,6] *and B. Ely*[7]*, (1)Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Healthcare Analytics Unit at the Center for Pediatric Clinical Effectiveness, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)PolicyLan, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Center for Pedaitric Clinical Effectiveness, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)Healthcare Analytics Unit at PolicyLab, The Children's Hospital of Philadelphia, Philadelphia, PA, (6)The Center for Pediatric Clinical Effectiveness, The Children's Hospital of Philadelphia, Philadelphia, PA, (7)University of Pennsylvania School of Nursing, Philadelphia, PA*

Background: Children with Autism Spectrum Disorders (ASD) display a range of language abilities and behaviors to reflect symptoms from illness or injury that challenge interpretation in the health care environment that, in turn, impact evaluations and appropriate treatment, possibly leaving these individuals a vulnerable population within health care systems. The overwhelming nature of the emergency department (ED) environment as point of entry for diagnosis and treatment of abdominal pain may also contribute to the challenging assessment of the child with ASD. In addition, many providers of emergency medical services are largely unprepared to accommodate and adapt communication and practices to identify and meet the needs of individuals with social communicative differences. Importantly, delay in diagnosis for acute appendicitis may lead to increased morbidity, adding to length of stay, cost, and resource utilization.
Objectives: 1) To evaluate differences in the administration of analgesia between neurotypical (NT) individuals and children with ASD diagnosed with appendicitis in the ED and 2) to compare rates of complicated appendicitis (perforated or with peri-appendiceal abscess) among NT individuals and those with ASD at the time of diagnosis in the ED using the Pediatric Health Information System (PHIS), a comparative national database.

Methods: Retrospective case-control study of children 6-18 years of age with an ED visit for appendicitis between 2005 and 2015. Coarsened exact matching was used to match ASD children to NT controls within each hospital based on age, sex, race, ethnicity, ICD-9 diagnosis, and year of hospitalization. Logistic regression was used to investigate the association between ASD status and medication receipt. Outcomes included receipt of opioid or non-opioid analgesic within the first 48 hours of an ED visit. Comparison of the rates of complicated versus simple appendicitis in ASD and NT children was conducted before matching. Results of weighted logistic regression and truncated negative binomial regression models are reported.

Results: 126,412 children with appendicitis were identified in PHIS. The matched sample consisted of 889 children with ASD (>88% male, 60% 7-18 years of age, 77% white) and 35,672 NT controls. Receipt of opioids or non-opioid analgesics was not found to be statistically different between the two groups. Compared to NT controls, children with ASD with appendicitis had no significant difference regarding: receipt of no medication [0.67% vs. 0.97%; OR= 0.694 (0.309, 1.559), p= 0.38] and receipt of any pain medication [54.22% vs. 54.96%; OR=0.971 (0.848-1.109), p=0.66]. A significant difference (<0.0001) was found between children with ASD and NT controls for complicated appendicitis (N, ASD=355, 37.1% vs. N, NT=37,520, 29.9%).

Conclusions: Children with ASD have increased rates of complex appendicitis compared to those without ASD suggesting limited access to care, caregiver difficulty in assessing pain and others relevant symptoms in their child with ASD or provider difficulty in evaluating this population. However, receipt of analgesia in the ED for appendicitis did not differ significantly between populations of children with ASD and NT peers.

215

186.215 Efficacy of a New Family-Based Cognitive-Behavioral Intervention for Insomnia in Children with ASD

***M. O. Mazurek**[1], W. S. Chan[2], M. Munoz[3], J. E. Muckerman[4], T. N. Takahashi[4], S. Takamatsu[3], P. Sahota[3] and C. S. McCrae[3], (1)University of Virginia, Charlottesville, VA, (2)Psychiatry, Dartmouth College, Lebanon, NH, (3)University of Missouri, Columbia, MO, (4)Thompson Center for Autism & Neurodevelopmental Disorders, University of Missouri, Columbia, MO*

Background: Insomnia affects up to 80% of children with autism spectrum disorder (ASD) and has significant detrimental effects on daytime functioning and well-being for both children and parents. Despite the clinical importance of this issue, empirically supported treatments for insomnia in children with ASD are lacking. Cognitive-behavioral therapy for childhood insomnia (CBT-CI) represents a promising approach, but it has not been previously tested in children with ASD.

Objectives: The objective of this study was to test the preliminary efficacy of a family-based cognitive behavioral therapy for insomnia that was specifically adapted for children with ASD (CBT-CI-A). Primary outcomes included child and parent sleep (subjective and objective), child daytime behavior, and parent fatigue.

Methods: Participants included 31 children with ASD and insomnia (ages 6-12, 74% male) and their parents (ages 28-48, 13% male) who participated in an 8-session clinical trial of the newly developed CBT-CI-A. Nineteen families participated in face-to-face therapy sessions, while twelve families participated in remote sessions delivered via videoconferencing technology. Child and parent sleep were assessed by actigraphy (Actiwatch-L®, Respironics) and daily completion of electronic sleep diaries for two weeks at baseline, post-treatment, and 1-month follow-up. Parent diaries assessed daily fatigue (0–100 scale). Averages were calculated across each two-week assessment period for sleep onset latency, total wake time, total sleep time, sleep efficiency, and fatigue (parent only). Child daytime behavior was assessed at each time point via the Aberrant Behavior Checklist.

Results: Data from the face-to-face delivery condition are presented here, but complete data for the entire sample and comparisons between delivery-format will be included in the final presentation. For the face-to-face delivery, paired samples t-tests revealed moderate-large improvements in child objective sleep [onset latency (~18 minutes), total wake time (~41 minutes), total sleep time (~17 minutes), efficiency (~6%); within group effect sizes (*ES*)=.52-1.28], and moderate-large improvements in child subjective sleep [onset latency (~30 minutes), total wake time (~44 minutes), sleep efficiency (~6%); *ES*=.68-1.80], bed/waketime regulation (~30 minutes each, *ES*=.76-2.17), and daytime behavior [irritability, social withdrawal, stereotypy, inappropriate speech; *ES*=.52-.86]. Treatment gains were maintained at 1-month follow-up [*ES*=.25-2.23]. Parent improvements were found in objective total sleep time (~19 minutes, *ES*=.41), subjective sleep [onset latency (~10 minutes), wake after sleep onset (~12 minutes), total wake time (~25 minutes), sleep efficiency (~5%); *ES*=.49-1.01)], and fatigue (~10 points, *ES*=.52). Parent treatment gains were generally maintained with additional objective sleep improvements at 1-month follow-up [onset latency (~5 minutes), wake after sleep onset (~5 minutes), total wake time (~10 minutes); *ES*=.45-.98].

Conclusions: The results of this pilot study suggest that the newly developed CBT-CI-A is an efficacious treatment for insomnia in children with ASD and their families. Sleep markedly improved for children with ASD and their parents according to both objective and subjective measures. Importantly, children's daytime behaviors also improved. These findings suggest that CBT-CI-A is a promising treatment for insomnia in children with ASD. Larger scale studies are needed to further evaluate the effectiveness of this treatment in larger samples using randomized clinical trial designs, active control groups, and long-term follow-up.

186.216 Emotional Coherence Difficulties in Preschoolers with Autism: Evidence from Internal Physiological and External Communicative Discoordination

***H. J. Nuske**[1], D. Hedley[2], L. Tomczuk[3], E. Finkel[4], P. Thomson[5] and C. Dissanayake[2], (1)Center for Mental Health, University of Pennsylvania, Philadelphia, PA, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Neuroscience Department, Dickinson College, Carlisle, USA, Carlisle, PA, (4)Department of Psychology, University of Pennsylvania, Philadelphia, PA, (5)Olga Tennison Autism Research Center, La Trobe University, Bundoora, Australia*

Background: The ability to communicate stress is important as it signals to others that help is needed and, for young children, creates learning opportunities around managing emotions. Many children with Autism Spectrum Disorder (ASD) have difficulties clearly expressing emotions and communicating these expressions to others. What is not clear, however, is whether this represents a general reactivity difference in this population, or whether this means that despite reacting physiologically, children may not be communicating this stress with expressive behaviors (e.g., facial expressions). Hence, children with ASD may have difficulties with coordinating internal and external reactions, or *emotional coherence*, relative to typically developing (TD) children.

Objectives: The aim in the study was to determine the association between internal physiological emotional reactivity and external communicative emotional reactivity in children with ASD, relative to TD children.

Methods: Preschoolers with autism (ASD) and TD preschoolers watched a relaxing video (resting state task) and participated in a low-level stress task from the Laboratory Temperament Assessment Battery (the Transparent Box Task), whilst wearing a wireless ECG monitor to measure heart rate (beats per minute), as an index of physiological reactivity. Children's emotional communication behaviors (facial, vocal and bodily expressions) were coded offline by reliable coders, who were blind to diagnostic group and study aims.

Results: Preliminary results (n=20 TD, 16 ASD) showed that whilst all children reacted to the low-level stress task, relative to the resting state task, by displaying emotional communicative behaviors, only in the TD group was children's increase in heart rate correlated for facial (r = .36, p = .06) and vocal expressions (r = .33, p = .08; bodily expressions and heart rate were not correlated in the TD group: r =- .06, p = .40.) For the ASD group, no associations were found between their internal physiological and external communicative reactions (heart rate and facial reactivity: r = -.24, p = .21; vocal reactivity: r = -.20, p = .25; bodily reactivity: r = -.19, p = .26). See Figure 1 and 2 for vocal reactivity scatterplots as an example.

Conclusions: Children with ASD may have more difficulty expressing physiological emotional reactions via communicative behaviour, relative to their peers. Given that co-regulation strategies (e.g., driven by a social partner, such as mother) which are prevalent in preschoolers, and associated learning opportunities for emotion management, are reliant on the child first signalling their stress to others, such an expressive impairment may contribute to emotion regulation difficulties downstream. A 2-year follow-up of the sample is currently underway and presentation will include results on prediction of emotional coherence to emotion regulation and challenging behaviour in the children. Given the recent technological advances in wearable biosensing, our results suggest incorporation of heart rate signalling in intervention for children with ASD may show promise, through signalling children's stress on their behalf, allowing parents and teachers to intervene and create learning opportunities for emotional expression and regulation.

217 **186.217** Examining the Impacted of the Severity of Attention Deficit/ Hyperactivity Disorder Symptoms on the Cognitive Flexibility in Children and Adolescents with Autism Spectrum Disorders.

***Y. C. WU*[1]**, *S. S. F. Gau[2] and S. L. Gu Hwang[1], (1)Department of Occupational Therapy, Chang Gung University, Taoyuan City, Taiwan, (2)Department of Psychiatry, National Taiwan University Hospital & College of Medicine, Taipei, Taiwan*

Background: Autism spectrum disorder (ASD) is a lifelong neurodevelopmental disorder. Symptoms of the manifest ASD as impairments in cognitive flexibility, the ability to adaptive switch among multiple representations as a function of changing relevant cues in the environment. One of the most commonly used of cognitive flexibility is the Wisconsin Card Sorting Test (WCST), but the previous studies on ASD have yielded mixed results, some studies showed impairments in cognitive flexibility in ASD than typical development (TD), but some argued that there are no differences between two groups.

Previous studies have described that children with ASD (30-50%) suffer from comorbid with Attention deficit/ hyperactivity disorder (ADHD) symptoms, and several studies showed children with ADHD had poor performance in WCST. To date, only few studies examine the severity of comorbid ADHD symptoms, whether would influence the performance of cognitive flexibility in ASD.

Objectives: Thus, previous studies argued the inconsistencies might be due to differences in participant characteristics like age, IQ, and co-occurring ADHD symptoms.

The aim of this study was: (1) to investigate whether children and adolescents (7-17 years old) with ASD group shows cognitive flexibility impairments than matched TD group on WCST performance, (2) to investigate the influence of comorbid ADHD symptoms on WCST performance.

Methods: A total of 141 ASD and 94 TD were matched by sex (ASD vs TD, male/ female: 126/15 vs 79/15), age (12.22 ± 2.20 vs 12.49 ± 2.08) and Wechsler full-scale intelligence (FIQ) (106.26 ± 11.91 vs 108.57 ± 10.73).

The computerized version of WCST was selected as cognitive flexibility measures. Symptoms in ASD were assessed by Autism Diagnostic Interview-Revise (ADI-R), and in ADHD were assessed by Swanson, Nolan, and Pelham rating scale version IV (SNAP-IV).

For the analysis, firstly, group comparisons of demographic data were used independent t-tests. Secondly, Cohen's *d* was calculated to quantify the magnitudes of group effects in the differences of WCST performance. Lastly, the differences of WCST performance were examined through analysis of covariance (ANCOVA), whereby the analyses were controlled for the effects of the age FIQ and comorbid ADHD symptoms covariates.

Results: A statistical comparison of Demographic revealed no significant difference between ASD and TD group (Table 1).

The independent t-tests showed the ASD group performed significantly worse with the TD group on the WCST index (Figure1), including the trials administered (p<.0001), total correct (p<.0001), total errors (p= 0.062), % perseverative response (p= 0.0011), % perseverative errors (p= 0.0026), and the medium effect size was found (Table 2).

The analysis of ANCOVA revealed the significant differences between the groups in the trials administered, total correct, total errors, %perseverative response, %perseverative errors, and no main and interactive effects of age-FIQ and age-FIQ-comorbid ADHD symptoms of WCST performance (Table 2).

Conclusions: In the present study, we have replicated previous results reporting impairment of the ASD group in cognitive flexibility (WCST performance), and confirmed the deficits of cognitive flexibility were associated with ASD diagnosis, rather than the severity of the comorbid of ADHD symptoms.

218 **186.218** Exploring Shared Mechanisms across Autism and Depression to Inform Emotional Health Interventions in ASD

***K. Gotham*[1]**, *G. T. Han[2], K. E. Unruh[3], R. N. Crist[4] and J. W. Bodfish[5], (1)Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt University, Nashville, TN, TN, (3)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (4)Vanderbilt University, Cambridge, MA, (5)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN*

Background: Depression is a leading form of clinical impairment for adults with ASD, with reported rates as high as 38-70% in convenience samples. Depressed mood in ASD impairs daily functioning, heightens the need for special services and medications, and places an increased burden on caregivers. By learning about the phenomenology and causal pathways of depression in ASD, we can begin to develop screening, assessment, and intervention protocols tailored to the specific needs of this population, particularly underserved adults with ASD.

Objectives: To identify potential contributors to depressed mood in ASD by comparing adults with ASD, typically developing adults with depressive disorders (TD-dep), and never-depressed controls (TD-con) on several phenomena associated with depression, including repetitive thinking, attentional bias and neural response to negative emotional material, and social anhedonia.

Methods: Our current sample of n=112 will increase significantly by May 2018. This abstract reflects findings from manuscripts in preparation based on a preliminary subset of n=53 adults aged 18-35 with verbal IQ>80. Cohorts included ASD (n=21), TD-dep (n=13), and TD-con (n=19). Participants completed diagnostic assessments (including the Autism Diagnostic Observation Scale, second edition, and the Structured Clinical Interview for DSM-5 Disorders), self-report questionnaires (e.g., Beck Depression Inventory; Ruminative Response Scale; Anticipatory and Consummatory Interpersonal Pleasure Scale), and passive-viewing tasks employing emotionally-expressive faces, during which (1) pupil motility was used to index cognitive-emotional load in response to single faces emoting happy, sad, neutral, or angry expressions presented for 400 milliseconds then masked for 9 seconds, and (2) visual attention to emotional over neutral faces was quantified in a paired preference eye-tracking task.

Results: (1) When looking at brief-then-masked emotional faces, people with elevated depressive symptoms had faster, greater, and longer-lasting increases in pupil-indexed neural activation to sad stimuli *regardless of ASD status* (Figure 1.A). (2) Within ASD, distinct profiles of pupil response differentiated rumination in the context of depression versus general repetitive thinking (Figure 1.B). (3) The ASD group displayed significantly faster fixations to sad over neutral faces (t =-3.66, p=.002), and those with greater repetitive thinking spent more overall time on sad than neutral faces (Cohen’s d=.90, large effect); (4) Both the ASD and TD-dep groups displayed significantly decreased preference for happy faces compared to TD-con (F=15.79, p<.001; Figure 2). (5) Participants with ASD exhibited a similar pattern of social reward functioning as TD-dep, in which greater social ‘wanting’ was associated with the experience of loneliness and depressive symptoms.

Conclusions: We observed several parallels in cognitive, attentional, and emotional processing across our ASD and TD-dep samples in comparison to TD-controls. Specific findings indicate that rumination, negative attention bias, and social anhedonia may be best conceptualized as “depression-like” (rather than autism-specific) in treatment for adults with ASD. We also noted that our pupil results begin to isolate potential biomarkers of depression-specific and autism-specific cognitive-emotional processing. We will discuss existing treatments for rumination that may be adapted for the ASD population, as well as reward-based social skills training that may enhance emotional well-being in adults with ASD.

219 **186.219** First Evidence of the Efficacy of a Novel Positive Emotion Regulation Training for Individuals with Autism Spectrum Disorder

A. C. Samson[1,2], *A. Zaharia*[1] *and D. Sander*[1], *(1)Swiss Center for Affective Sciences, University of Geneva, Geneva, Switzerland, (2)Department of Psychiatry and Behavioral Science, Stanford University School of Medicine, Stanford, CA*

Background: Emotional disturbances including irritability and associated comorbidities are of high prevalence in individuals with Autism Spectrum Disorder (ASD) and posit one of the main reasons why parents of children with ASD reach out for help. Over the past decade, there is mounting evidence that maladaptive emotion regulation plays a crucial role in the emergence of emotional disturbances. Moreover, despite the adaptive functions of positive emotions, none of the interventions targeting emotional disturbances in individuals with ASD had a particular focus on positive emotions.

Objectives: The goal of the present study was to develop and test the efficacy of a novel psycho-educative multi-media training that aims at increasing emotion regulation skills and positive emotions in individuals with ASD.

Methods: Twenty-nine high-functioning individuals with ASD (mean age: 17.76, SD=5.50 years, 5 females) completed three sessions of the psycho-educative positive emotion regulation training with 18 participants in the training group and 11 participants in the waitlist control group. The two groups did not differ regarding age, gender, or ASD symptom severity as assessed with the Social Responsiveness Questionnaire and the Autism Quotient. The training consisted of three individual sessions that aimed at increasing emotional awareness and the use of three adaptive emotion regulation strategies (focus on positive elements in daily lives, positive cognitive reappraisal, and positive emotional expressions) by providing theoretical background information, examples supported by multi-media elements such as animated cartoons, and interactive exercises and homework for the participants. Participants and their parents completed questionnaires on emotion reactivity, well-being, emotion regulation, alexithymia, and problematic behaviors pre- and post training. The training was delivered in person or online (with optional assistance via skype). 55.2% completed the training with in person, 17.2 via skype with assistance, and 27.65% alone.

Results: Compared to the waitlist control group which did not show changes, individuals that completed the training showed an increase in the use of the emotion regulation strategies “focus on positive” ($t(17)=-2.51$, $p<.05$) and cognitive reappraisal ($t(17)=-2.35$, $p<.05$) and as well as a decrease in negative emotions ($t(17)=3.55$, $p<.01$). Interestingly, alexithymia did not have a moderating effect on any of these findings.

Conclusions: This brief psycho-educative training shows promising effects to target emotional disturbances in individuals with ASD. This training may be useful to add to more comprehensive intervention programs targeting emotional disturbances in ASD.

220 **186.220** High Risk for Severe Emotional Dysregulation in Psychiatrically Referred Youth with Autism Spectrum Disorder: A Controlled Study

J. Wozniak[1], *G. Joshi*[2], *M. Fitzgerald*[3], *S. V. Faraone*[4], *R. Fried*[5], *M. Galdo*[5], *A. Belser*[2] *and J. Biederman*[2], *(1)Massachusetts General Hospital / Harvard Medical School, Boston, MA, (2)Pediatric Psychopharmacology and Adult ADHD, Massachusetts General Hospital, Boston, MA, (3)Pediatric Psychopharmacology, Massachusetts General Hospital, Boston, MA, (4)Psychiatry, SUNY Upstate Medical University, Syracuse, NY, (5)Massachusetts General Hospital, Boston, MA*

Background:

Prevalence of ASD is considerably higher in psychiatrically referred populations of youth, ranging from 2-14%. Psychiatric referrals of children with ASD are frequently driven by emotional and behavioral problems. Emotional dysregulation (ED) is characterized by poor self-regulation, including symptoms of low frustration tolerance, impatience, quickness to anger, and emotional reactivity. Within the context of ASD, researchers have defined ED in distinctive ways for assessing deficits in regulation of emotions. We have operationalized different levels of ED using a unique profile of the Child Behavior Checklist (CBCL) (Achenbach, 1991) consisting of elevated scores of the Anxiety/Depression, Aggression, and Attention subscales. The ED profile on the CBCL (CBCL-ED) can help identify moderate [≥1SD and <2SD; Deficient Emotional Self-Regulation (DESR)] or severe [≥2SDs; Severe Emotional Dysregulation profile (SED)] levels of ED in children with emotional and behavioral difficulties. Although deficits in regulation of emotions have been documented in children with ASD the prevalence of ED based on the varying severity levels of CBCL-ED profile and whether the two sub-forms of ED are clinically helpful in distinguishing distinct levels of deficits in children with ASD remains unclear. Considering the empirical nature of the CBCL, its excellent psychometric properties, and its ease of implementation, documenting the magnitude and severity of ED per CBCL operationalized criteria in ASD populations remains an area of very high clinical importance. The knowledge derived from this work could translate into improved recognition and therapeutics for ASD children at risk for differently compromised courses and outcomes.

Objectives:

The main aim of the present study is to: 1) examine the prevalence of the two CBCL based ED profiles in youth with ASD; and 2) investigate whether the two severity levels of CBCL profiles for ED can help distinguish clinically distinct levels of deficits in ASD. We hypothesized that the two CBCL-ED profiles in youth with ASD would identify differentiating patterns of clinical correlates.

Methods:

ASD youth (N=123) were compared to youth with attention-deficit/hyperactivity disorder (ADHD) and healthy controls. We compared the prevalence of the two CBCL-ED profiles in psychiatrically referred population of youth with ASD to those with ADHD and to healthy controls (HC). Furthermore, we directly compared the demographic, psychopathological, and functional correlates associated with the two CBCL-ED profiles in youth with ASD.

Results:

The majority of psychiatrically referred youth with ASD had positive CBCL-ED profile that was significantly higher than in youth with ADHD (82% vs. 53%; p<0.001). The SED profile was significantly greater in ASD youth than ADHD (44% vs. 15%; p<0.001). In the presence of SED profile ASD youth suffered from greater severity of autism, associated psychopathology, and psychosocial dysfunction.

Conclusions:

There is a greater than expected prevalence of SED in psychiatrically referred youth with ASD that identifies distinct clinical correlates associated with severe morbidity and dysfunction.

221 **186.221** Identifying Associations Among Medical Comorbidities in Autism Spectrum Disorder.

A. Neumeyer[1]*, J. S. Anixt*[2]*, J. Chan*[3]*, J. M. Perrin*[4]*, D. S. Murray*[5]*, D. Coury*[6]*, A. Bennett*[7]*, R. A. Parker*[8] *and J. G. Farmer*[9]*, (1)Lurie Center for Autism Massachusetts General Hospital, Lexington, MA, (2)Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Massachusetts General Hospital, Boston, MA, (4)Harvard Medical School, Boston, MA, (5)Autism Speaks, Boston, MA, (6)Nationwide Children's Hospital, Columbus, OH, (7)Children's Hospital of Philadelphia, Philadelphia, PA, (8)Biostatistics, Massachusetts General Hospital and Harvard Medical School, Boston, MA, (9)Pediatrics, Massachusetts General Hospital, Boston, MA*

Background:

Much research has documented high rates of co-morbid medical conditions in children with autism spectrum disorders. This includes speech disorders, developmental delay, ADHD, hypotonia, seizure disorder, sleep disorders, anxiety, disruptive behavior, gastro-intestinal disorders such as constipation and feeding difficulties, pica, and eczema. Less is known about whether these commonly co-exist in the same children.

Objectives:

To determine clinically meaningful and statistically significant associations among co-occurring medical conditions in children with ASD that, if identified, could lead to better identification, treatment or understanding of the disease process.

Methods:

The Autism Speaks-Autism Treatment Network Registry includes over 7,000 well-phenotyped children with ASD. From the registry, we studied 2114 children between the ages of 17 months to 5 years old and 1221 children 6-17 years old at 20 sites. Diagnoses and problems were reported by clinicians upon subject enrollment, and were grouped into 12 core problems. We determined the observed prevalence (O) of co-occurring conditions and estimated the expected prevalence (E) across the network, adjusting for site variability in the prevalence of individual conditions. We used O/E rather than the relative risk, since O/E is invariant to the ordering of the conditions, whereas the relative risk depends on whether one is estimating relative risk for condition 2 given condition 1 or condition 1 given condition 2. P-values were calculated using a Cochran-Mantel-Haenszel test stratified by site. Once calculations were completed, we identified pairs of conditions co-occurring more frequently than expected (O/E > 1) and highlight those differences which were statistically significant. We also identified pairs of conditions co-occurring less frequently than expected (O/E < 1), but because of the small number of individuals in such a pair these were less likely to be statistically significant (figures 1, 2).

Results:

Among the 66 condition pairs for each age group, we confirmed previously identified associations such as sleep disorders and anxiety symptoms in older children. We found associations not previously described: feeding with sleep disorders (younger children only), constipation with sleep disorders, feeding with speech disorders, and constipation with speech disorders.

Conclusions:

An understanding of medical problems that co-occur in children more frequently than would be expected, as identified through innovative statistical strategies, provides an opportunity to better screen for and treat conditions that could have a related etiology (i.e. sleep and constipation), and, thereby, improve quality of life for individuals with ASD. For example, while feeding problems are frequent in ASD, they are usually attributed to sensory issues with oral motor function less commonly considered. The association of feeding with speech disorders suggests oral motor problems may be more common than typically appreciated. The association of feeding with sleep disorders is clinically recognized but may indicate upper airway or oral motor dysfunction as is seen in obstructive sleep apnea, or could indicate underlying sensory or behavioral regulation issues that impact both feeding and sleep. Children with constipation may experience sleep disruption due to discomfort which could also contribute to feeding problems.

222 **186.222** Longitudinal Study of Sleep and Co-Occurring Problems in Autism Spectrum Disorder

K. N. Medeiros[1]*, M. O. Mazurek*[2]*, A. M. Neumeyer*[3] *and B. A. Malow*[4]*, (1)Health Psychology, University of Missouri, Columbia, MO, (2)University of Virginia, Charlottesville, VA, (3)Pediatrics and Neurology, Massachusetts General Hospital, Lexington, MA, (4)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN*

Background: Autism spectrum disorder (ASD) is characterized by high rates of medical and behavioral comorbidities. Sleep problems are particularly detrimental, contributing to significant distress and impairment over and above the effects of primary ASD symptoms. Prior studies have found that sleep problems are associated with anxiety, stereotypic and challenging behavior, and sensory reactivity among children with ASD. However, the relations among these symptoms are not well understood. Studies to date have been primarily cross-sectional, meaning that directionality and causality cannot be determined. A better understanding of the longitudinal course and correlates of sleep problems in children with ASD would provide important insights into potential mechanisms and targets for treatment.

Objectives: The primary objective of this study was to describe the chronicity of sleep disturbance in children with ASD over time. The secondary objective was to understand the relations among sleep disturbance, internalizing symptoms, behavior problems, and sensory problems over time.

Methods: The data for this study included 514 children and adolescents with ASD (81% male, age M = 5.9, SD = 3.2) who were enrolled in the Autism Treatment Network Registry. Of the 2400 children assessed in this registry, 514 had baseline and longitudinal follow-up data on the variables of interest (M = 3.8 years later, SD = .62). Primary measures included the Children’s Sleep Habit Questionnaire, Child Behavior Checklist, Aberrant Behavior Checklist, and Short Sensory Profile. Structural equation models were used to examine the interrelationships among sleep problems and co-occurring symptoms over time, while controlling for IQ, age, gender, sleep medications, parent education, household income, and time between visits.

Results: Sleep problems at baseline were predictive of future sleep problems, even after controlling for covariates. Over time, 36% of the sample showed intensification of sleep problems and 44.4% showed improvement in sleep problems. Children were more likely to improve if their initial sleep problems were less severe. Neither age [F(2, 343) = .088, p =.915], IQ [F(2, 343) = 1.511, p = .222], gender [χ2 (2) = 1.285, p = .526], nor time between assessments [F(2, 343) = .977, p = .377] were related to the progression of sleep problems. In addition, parent education, household income, and use of sleep medications were unrelated to change in sleep problems (ps > .05). However, individuals were more likely to improve if their initial sleep problems were minor (r = -.490, p < .001). Initial anxiety predicted future sleep problems, and initial sleep problems predicted future attention problems and hyperactivity. Sleep and somatic complaints were interrelated over time; whereas, several other internalizing and externalizing symptoms were independent of sleep problems.

Conclusions: These longitudinal analyses provide insights into the nature, course, and development of sleep and other co-occurring problems in children with ASD, offering new directions for targeted interventions. Although further research is needed, the results suggest that addressing anxiety may improve sleep problems for some children with ASD, and that improving sleep may reduce attention problems and hyperactivity.

223 **186.223** Mapping Anxiety in Minimally Verbal Autistic Pupils

J. Galpin[1], *S. Millar*[2], *T. Andrews*[2], *P. Calzada*[2], *E. Ashcroft*[2] *and J. Gallagher*[3], *(1)The Bridge London Trust, London, United Kingdom, (2)The Bridge School, London, London, United Kingdom, (3)Whittington Health NHS Trust, London, United Kingdom*

Background: Autistic individuals are significantly more likely to experience clinically significant levels of anxiety than neurotypical peers. Better support for autistic individuals in managing anxiety would bring numerous benefits notably in support with behaviours that challenge. Addressing anxiety is also a priority for parents of autistic individuals. Better support requires a better understanding of anxiety 'triggers' for autistic individuals. Recent research in psychopathology has moved towards an understanding that conditions involve highly connected *networks* of symptoms. These networks are created by interactions and causal influences between symptoms. From this perspective, anxiety may develop as a result of prolonged interactions between various triggers. A networked understanding of anxiety may give a better understanding of how to provide more effective support.

Objectives: This study, co-produced by school-based professionals and parents, examined the viability of better understanding anxiety in minimally verbal autistic adolescents through the use of perceived causal relationship (PCR) scaling and network analysis in order to provide more direct support.

Methods: Anxiety triggers were identified for 18 pupils (16 male and 2 female) attending a government funded, special school in inner-city London. Pupils' ages ranged from 14 years 10 months to 17;7 (*M*=15;8, *SD*=1;9). Parents and professionals rated how frequently pupils experienced anxiety as a result of each trigger. The eight response options ranging between "Not at all in the past month" and "Daily or almost daily for most of the day" and scored 0-7, respectively. Parents and professionals then responded to causal association questions - the extent to which "trigger X" caused "trigger Y" and vice-versa. Response options were rated from 0-10 with 0, 5 and 10 denoting "Not at all", "Moderately cause," and "Strong cause" respectively. Mean Causal Association and Mean Causal Effect scores were calculated. To map anxiety a directed network of PCR scores was generated using the R-package qgraph. Nodes represented triggers and PCR scores were represented by edges between the nodes. The direction of the edges represented the direction of the perceived causal effect and the thickness indicated its strength. Centrality measures were used to examine which triggers were most influential (central) in the network.

Results: The network maps provided a clear, visual representation of the inter-relationship between anxiety triggers. Each pupil was readily identifiable from the maps giving a measure of face validity. Qualitative data collected from professionals and parents endorsed the network map as providing a clearer indication of specific triggers to target for support.

Conclusions: This study represents the first time network analysis has been used to map anxiety in minimally verbal autistic adolescents. It has promise as a method of assessing the inter-relationship of anxiety triggers as a means to direct more effective support. Future research should examine the extent to which targeting a high-centrality trigger for support initiates a beneficial therapeutic cascade that mitigates the impact of other triggers, addressing anxiety more effectively in terms of time and resources and more rapidly reducing individuals' distress.

224 **186.224** Measuring Autistic Traits in Adults Who Have Attempted Suicide

G. Richards[1,2], *R. Kenny*[3], *S. A. Cassidy*[1,4], *S. Griffiths*[3], *C. Allison*[1], *D. Mosse*[5], *R. Holt*[3] *and S. Baron-Cohen*[1,6], *(1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)NIHR CLAHRC East of England, Cambridge, United Kingdom, (3)University of Cambridge, Cambridge, United Kingdom, (4)School of Psychology, University of Nottingham, Nottingham, United Kingdom, (5)Department of Anthropology and Sociology, SOAS University of London, London, United Kingdom, (6)CLASS Clinic, Cambridgeshire & Peterborough NHS Trust, Cambridge, United Kingdom*

Background: Previous research suggests that adults with Autism Spectrum Conditions (ASC) have increased risk of experiencing suicidal thoughts and behaviours, and of dying by suicide. However, few studies have investigated the possible role of autistic traits in suicidal behaviour.

Objectives: To quantitatively measure autistic traits in adults who have attempted suicide, and to compare the findings with those reported in the general population.

Methods: An online questionnaire was advertised on suicide prevention websites, a psychology research participant database, and social media. Autistic traits were measured using the Autism Spectrum Quotient (AQ). 245 people accessed the survey, 168 of whom completed the AQ. Of these, 132 specified that they had attempted suicide. AQ scores for these participants were then compared to general population means published by Baron-Cohen et al. (2014).

Results: To determine that any effects observed were not driven by an overrepresentation of people with autism, those with diagnosed or suspected autism were removed from the analysis. After this, it was found that 40.6% of adults who had attempted suicide had an AQ score of 26 or above, which is a cut-off indicating potential clinical significance. AQ scores in this group (*M* = 22.45, *SD* = 8.67) were significantly higher than those of women (*M* = 17.1, *SD* = 7.6; *t*[2658] = 6.8, *p* < 0.001) and men (*M* = 20.3, *SD* = 7.8; *t*[1440] = 2.61, *p* = 0.009) from the general population. AQ scores were also significantly higher in adults who had attempted suicide more than once (*M* = 24.22, *SD* = 8.26) compared to adults who had attempted suicide on one occasion (*M* = 19.09, *SD* = 8.67), *t*(90) = -2.808, *p* = 0.006.

Conclusions: The current findings add to a growing literature that suggests elevated autistic traits are related to the likelihood of experiencing suicidal thoughts and behaviours. A better understanding of this area is urgently required to help reduce suicide risk in people with and without a diagnosis of autism.

225 **186.225** Mechanisms Underlying Thoughts of Self-Harm and Depression in Autism Spectrum Disorder: Findings from a Nationally Representative Sample

D. Hedley[1]*, M. Uljarevic*[2,3,4]*, K. R. Foley*[5,6]*, A. L. Richdale*[1,7] *and J. Trollor*[5,6]*, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (3)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, CA, (4)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (5)The University of New South Wales, UNSW Sydney, Australia, (6)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Queensland, Australia, (7)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Australia*

Background: Across the lifespan people on the autism spectrum experience extremely high rates of co-morbid psychopathology, the most common being anxiety and depression (Bellini, 2006; Hofvander et al., 2009; Lever & Geurts, 2016; Uljarevic et al., 2017), and sleep disorders (Humphreys et al., 2013; Richdale & Schreck, 2009). The high rate of depression in the autistic community is particularly concerning as this factor alone is likely to place many individuals at heightened risk of suicide (Hedley, Uljarević, Wilmot, Richdale, & Dissanayake, 2017). Indeed, recent research suggests risk for suicide, including suicidal ideation and death, is elevated in this population (Cassidy et al., 2014; Hirvikoski et al., 2016). However, and although there is emerging and promising work in this area, more theoretical work is needed to identify the mechanisms that might lead to increased risk of poor mental health outcomes, including depression, suicidal ideation and behavior, in the autistic population.

Objectives: The aim of the present study was to examine the associations between loneliness and social support, ASD trait severity, and depression and thoughts of self-harm in an Australian nationally representative sample of people on the autism spectrum.

Methods: Participants were 185 individuals (92 female; M_{age} = 37.11, *SD* = 15.41 years) who were participating in one of two nationwide longitudinal studies (school leavers, adults) into autism. Participants self-reported a formal diagnosis of ASD and, for inclusion in the present study, were required to return a score > 65 on the AQ-Short. Participants also completed the University of California Los Angeles Loneliness Scale-Short Form (ULS-8) (Hays & DiMatteo, 1987), the Social Support Questionnaire-Shortened Version (SSQ-6) (Sarason, Sarason, Shearin, & Pierce, 1987), and the Patient Health Questionnaire-9 (PHQ-9) (Kroenke, Spitzer, & Williams, 2001), which includes a question concerning self-harm.

Results: Forty-nine percent of participants returned scores in the clinical range for depression and 36% reported recent suicidal ideation. Females, comprising almost 50% of the sample, returned higher depression scores than males, however no differences were identified between males and females in terms of self-harm. Regression analyses revealed that loneliness, satisfaction with social support and ASD traits predicted depression scores, and satisfaction with social support and depression predicted thoughts of self-harm. Path analysis showed that ASD trait severity was independently related to depression, the effect of number of social supports on depression was mediated by loneliness and satisfaction with social support, and that effects of loneliness and satisfaction with social support on self-harm were mediated by depression. The pattern of relationships was nearly identical for males and females.

Conclusions: This study identified high rates of depression and self-harm in a nationally representative Australian population sample. The finding that ASD traits independently predict depression suggests that autism may present a risk factor for the development and maintenance of psychiatric disturbance. Our model further suggests that loneliness and social support operate respectively as protective and risk factors for depression and self-harm in autism.

226 **186.226** Parent Ratings of Emotion Regulation in Children with and without ASD Differ Based on Level of Psychosocial Functioning

M. Gurm[1] *and G. Iarocci*[2]*, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Simon Fraser University, Burnaby, BC, Canada*

Background: A child's emotion regulation is associated with their psychosocial functioning (e.g., McDowell *et al*., 2002). Parent ratings indicate that children with Autism Spectrum Disorder (ASD) have more challenges with emotion regulation than their typically developing (TD) peers (Rieffe et al., 2011). Difficulties regulating emotions may explain the high co-morbidity with mental health concerns in individuals with ASD (Mazefsky *et al.,* 2013) as compared with their age matched TD peers (e.g., Samson *et al.,* 2015). However, emotion regulation has not been studied in groups of children matched on mental health concerns.

Objectives: The objectives of the current study were to 1) replicate findings of group differences in emotion regulation between ASD and TD groups, and 2) examine group differences in emotion regulation when ASD and TD groups are categorized based on overall psychosocial functioning (as a proxy for mental health).

Methods: Eighty-five children (age 7-12, IQ >80) and their parents were included in this study (43 ASD). Data was collected at a summer research camp over several years. Parents provided family demographic information and completed the Behavioural Symptoms Index (BSI) of the Behaviour Assessment System for Children-2nd edition (Kamphaus & Reynolds, 2004), and the Emotion Regulation subscale of the Multidimensional Social Competence Scale (MSCS;Yager & Iarocci, 2013). The BSI is an overall composite of psychosocial functioning that includes scales on hyperactivity, depression, aggression, atypicality, withdrawal, and attention problems. The MSCS has 7 distinct subscales including emotion regulation and an overall rating of social competence. Children were sorted into four independent groups based on diagnostic status and the BSI: 1) TD with low BSI (n=21), 2) TD with high BSI (n=21), 3) ASD with low BSI (n=21), and 4) ASD with high BSI (n=22).

Results: Compared to TD children, children with ASD had more challenges with emotion regulation (t=2.56, p=.01, d=.56) and higher BSI scores (t=-2.71, p<.01, d=.59). An analysis of variance found significant differences in emotion regulation between the four groups (F=21.59, p<.01). A Tukey post-hoc analysis revealed that both children with and without ASD and high BSI did not differ significantly from one another in their parent-reported emotion regulation (p=.69). Children with and without ASD and low BSI were significantly different in emotion regulation compared to all other groups (p<.03).

Conclusions: Consistent with previous research and the hypothesis that emotion regulation is associated with mental health problems, our results confirm that children with ASD have more challenges with emotion regulation than their non-ASD peers. However, when children with ASD are compared to children without ASD who also have similarly high levels of difficulties in psychosocial functioning, there are no significant differences in emotion regulation between groups. This suggests that there may be important similarities in children with and without ASD with poor psychosocial functioning. By comparing children with and without ASD with similar levels of psychosocial functioning we may be able to learn more about what is common about emotion regulation across groups and also what is unique in children with ASD. Implications for future research will be discussed.

227 **186.227** Predicting Poor Sleep Quality in Young Adults on the Autism Spectrum

A. L. Richdale[1], *L. P. Lawson*[2] *and M. Uljarevic*[3,4], *(1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, Australia, (3)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (4)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA*

Background: Poor sleep quality, primarily insomnia symptoms, is commonly reported in individuals on the autism spectrum across the lifespan. Poor sleep quality in autism has been associated with problematic behaviours and poor mental health, but most research is in children under 18 years. Arousal has been hypothesised to underlie insomnia symptoms in both autism and in non-autistic populations. Consistent with an arousal hypothesis, anxiety, cognitive and somatic pre-sleep arousal, and sensory modulation have been shown to be associated with poor sleep in children with autism. However, little is known about the predictors of poor sleep quality in older cohorts.
Objectives: Our aim was to examine the ability of factors associated with arousal to predict sleep problem classification in young adults on the autism spectrum.

Methods: Participants were 64 young people on the autism spectrum, with a mean age of 19.06 (SD=2.56) years (70% male) who are members of the Australian Longitudinal Study of School Leavers with Autism (SASLA). Their mean Autism Quotient-Short (AQ) total score was 76.50 (SD=10.25; clinical screening cutoff >65). Our measures associated with arousal were sensory interests (Repetitive Behaviours Questionnaire-Adult [RBQ-Sensory]; 3 items), autonomic symptoms (COMPASS-31; 31 items), and intolerance of uncertainty (transdiagnostic factor underlying anxiety [IU-12]; 12-items). The Pittsburgh Sleep Quality Index (PSQI) was used to classify sleep quality.

Results: All variables except age were significantly associated with PSQI total score (all $p < .01$), and females had significantly higher COMPASS-31 and IU-12 scores than males (all $p < .05$). Fifty percent of males, and 63% of females had a PSQI score greater than 5 ($p = .49$). A logistic regression was used to classify membership of the sleep problem (PSQI > 5) and no sleep problem (PSQI < 6) groups. The independent variables entered were gender, AQ, RBQ-Sensory, COMPASS-31 and IU-12. The model was significant ($p = .001$) and explained between 29.8% and 39.8% of variance, and correctly classified 77.2% of sleep cases with a positive predictive value of 79.3%. Only RBQ-sensory made a significant unique contribution to the model, with an OR of 1.83.

Conclusions: We have identified that factors associated with arousal are significantly associated with poor sleep quality among young adults on the autism spectrum. Further, it was found that sensory interests were uniquely associated with an increased likelihood of having poor sleep quality. Sensory issues have previously been reported to be a predictor of poor sleep in children with autism and non-autistic infants, children and adults. Given the potential deleterious effects of poor sleep, it is important to understand variables associated with poor sleep in autism as this informs development of prevention and intervention strategies, and such variables may be targets for intervention.

228 **186.228** Psychiatric Comorbidity and Sex Bias in Adults with Autism Spectrum Disorder

K. J. Feldman[1], *A. J. Fischer*[1], *J. Davis*[2], *H. Coon*[3] *and D. A. Bilder*[3], *(1)University of Utah, Salt Lake City, UT, (2)Educational Psychology, University of Utah, Salt Lake City, UT, (3)Psychiatry, University of Utah, Salt Lake City, UT*

Background:
Individuals with ASD frequently suffer from co-occurring psychiatric disorders with prevalence estimates ranging from 11-80%. The most commonly reported co-occurring psychiatric conditions are depression, obsessive-compulsive disorder (OCD), and anxiety. Psychiatric comorbidities provide accessible targets for intervention that can improve the quality of life of adults with ASD, necessitating an understanding of their prevalence rates in this population.

Objectives:

The aims of this study were to report the prevalence of co-occurring psychiatric conditions and the sex bias of comorbidity in a large sample of adults with ASD in comparison to a population-based control cohort.

Methods:

ASD case status (N=411) was determined by in-person assessments through ASD phenotyping protocols within the University of Utah Autism Research Program. ASD cases were matched to controls ($N = 2055$) within the Utah Population Database (UPDB) in a 1:5 ratio by age, sex, and duration of Utah residence (overall sample mean age = 31.14, range = 18-65; 87.1% male). Medical record diagnostic codes were used to identify the presence of co-occurring psychiatric disorders by linking cases and controls within the UPDB to diagnostic records from the two largest healthcare systems in Utah. Diagnostic codes were collapsed into the following categories: anxiety, OCD, depression, expansive mood, and schizophrenia. Chi-square analyses were used to compare the comorbidity frequency between cases and controls and between males and females within each cohort. Comparisons were considered statistically significant at the < 0.05 level.

Results:

The most common co-occurring psychiatric conditions in the ASD cohort were anxiety (47.4%), expansive mood (27.7%), and depression (18.0%). Comparison of psychiatric disorders between adults with and without ASD is provided in Table 1. Psychiatric conditions overall and categorically were significantly more prevalent in adults with ASD ($p < 0.001$).

Frequencies of psychiatric conditions were compared by sex within each cohort (Table 2). As expected, females in both cohorts experienced an increased rate of anxiety (ASD $p = 0.021$; control $p = 0.015$). Compared to their male counterparts, females in the control cohort, but not ASD cohort, experienced a significantly higher rate of depression (9.1% vs. 5.3%, $p = 0.013$; 18.9% vs. 17.9%, p = 0.861, respectively). Females in the ASD cohort had higher rates of OCD than males (28.3% vs. 15.9%, $p = 0.027$).

Conclusions:

These results confirm previous findings that adults with ASD experience increased rates of co-occurring psychiatric disorders, demonstrating the importance of identifying, and subsequently treating, these disorders in this population. Sex biases observed in the ASD cohort differed from the control cohort for depression and OCD. Psychiatric disorders commonly reported as having a male bias in the general population appeared in the context of ASD either equally between males and females (schizophrenia) or more commonly in females (OCD). Further in-person assessment is merited to characterize phenotypic and physiologic differences accompanying psychiatric comorbidity in adults with ASD.

229 **186.229** Sleep and Attention in Children with ASD-Associated Gene-Disruptive De Novo Mutations and Idiopathic ASD

ABSTRACT WITHDRAWN

Background: Sleep difficulties are common in autism spectrum disorder (ASD) and are especially evident in children with ASD-associated gene-disruptive *de novo* mutations (LGDMs), such as *CHD8* and *DYRK1A*. Despite extensive knowledge of comorbid sleep issues in ASD, little is known about the complex interplay between the genetic etiologies of ASD, sleep, and daytime attentional skills.

Objectives: We had two primary aims: (1) To characterize neural patterns of attention associated with parent-reported sleep issues; (2) To assess whether these patterns were more severe for children with an ASD-associated LGDM. We hypothesized that children with ASD and sleep problems may showcase poor attention, as evident by reduced discrimination between frequent and novel conditions and faster patterns of habituation on the Novelty P300 experiment. For children with ASD-associated LGDM we expected this pattern to be more robust.

Methods: Participants (*N* = 95) included children with an ASD-associated LGDM and idiopathic children with ASD without a known LGDM (NON; see Table 1 for characterization). Child attention was indexed using EEG while children watched a video and passively listening to sounds in an auditory oddball paradigm with a frequent condition (70%), an infrequent pitch deviant condition (15%), and an infrequent novelty deviant condition (15%). We focused on condition differences between the frequent and novelty deviant condition for the central P3a ERP component (180-350 ms). We used a single-trial approach to track dynamic patterns of attention (i.e., the variability of the P3a over the course of the experiment). Caregivers reported current sleep problems during a structured interview that included subdomains of daytime tiredness, problems with sleep onset, and nighttime awakenings.

Results: Multilevel models revealed a significant interaction between condition and sleep problems, $F(1, 9156) = 8.03$, $p = .004$, indicating less condition discrimination for children with sleep problems. For children with sleep problems, novelty habituation was more rapid (i.e., amplitude reducing more quickly) for children with sleep problems, $F(1, 137) = 3.18$, $p = .07$ (see Figure 1). There were no ERP differences between LGDM and NON among children without sleep problems. However, among those with sleep problems, LGDM children exhibited reduced condition discrimination relative to NON, especially in children who exhibit daytime tiredness and difficulties falling asleep.

Conclusions: These results confirm prior reports that sleep problems interfere with neural mechanisms of daytime attention and extend our understanding to dynamic patterns of daytime attention. Specifically, reduced novelty discrimination (i.e., attention orienting in response to infrequent, novel sounds) in children with ASD and sleep problems is in part due to rapid novelty habituation. Consequences of sleep problems were evident in both NON and LGDM groups; however, children with a LGDM did exhibit more severe attention disruptions particularly related to daytime tiredness and difficulties falling asleep. Further exploration of sleep problems in genetic subtypes of ASD, such as *CHD8* and *DYRK1A*, can inform the interaction between sleep and etiological contributions to ASD. We will discuss the biological implications at the intersection of sleep problems, dynamic attention, and genetic subtypes of ASD.

230 **186.230** Social Anhedonia As a Vulnerability Factor for Depression in Adults with ASD

G. T. Han[1] *and K. Gotham*[2], *(1)Vanderbilt University, Nashville, TN, TN, (2)Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN*

Background: Deficits in social reward processing have been associated with the onset, severity, and maintenance of depressive symptoms in the general literature. Social anhedonia, or reduced interest or pleasure in social stimuli, may represent a similar vulnerability factor for co-occurring depressive symptoms in individuals with ASD. In the typically developing (TD) population, lack of motivation to engage in rewarding experiences – or disrupted anticipatory ('wanting') pleasure – has been associated with increased distress due to perceived social isolation, or loneliness. In ASD, a less established body of work has suggested both decreased social anticipatory ('wanting') and consummatory ('liking') pleasure compared to TD counterparts, with some studies suggesting a particular deficit in social 'wanting' that is related to ASD symptom severity.

Objectives: To examine anticipatory and consummatory social and non-social pleasure as contributors to loneliness and depressed mood in adults with ASD compared to typically developing adults with depressive disorders (TD-dep) and never-depressed controls (TD-con).

Methods: A total of n=101 adults aged 18-35 with verbal IQ>80 were recruited from the three cohorts (ASD, n=44; TD-dep, n=28; TD-con, n=29). All participants completed diagnostic screening and testing, as well as self-report measures of capacity to experience social pleasure (Anticipatory and Consummatory Interpersonal Pleasure Scale; ACIPS), non-social pleasure (Temporal Experience of Pleasure Scale; TES), autism spectrum traits (Social Responsiveness Scale; SRS), loneliness (Loneliness in Context Questionnaire; LiCQ), and depressive symptoms (Beck Depression Inventory-II; BDI).

Results: The ASD and TD-dep groups did not differ significantly on measures of social and non-social pleasure, for both anticipatory and consummatory dimensions. However, both ASD and TD-dep groups showed decreased capacity for social and non-social pleasure compared to TD-con. The ASD cohort reported greater loneliness and depressive symptoms than TD-con, but less than TD-dep. In the whole sample (and replicated in ASD alone), there was a significant cross-over interaction between capacity for social pleasure and ASD traits on loneliness ($t(98)=-2.36$, $p=0.02$): individuals with greater capacity for social pleasure demonstrated a positive relation between ASD traits and loneliness, whereas individuals with decreased capacity for social pleasure exhibited the opposite effect (Figure 1). This moderation effect was not present for the measure of non-social pleasure. Finally, the ASD and TD-dep groups were combined to examine predictors of depressive symptoms trans-diagnostically. When controlling for social and non-social pleasure, loneliness, and ASD traits as predictors of depressive symptoms in a multiple regression framework, only loneliness was a significant predictor of BDI-II scores.

Conclusions: Results indicate that individuals with ASD exhibit a similar profile of capacity for social and non-social pleasure compared to TD-dep, in which 'liking' and 'wanting' components are both diminished compared to TD-con. In our transdiagnostic sample, increased ASD traits were associated with greater loneliness for individuals with greater capacity for social pleasure. Interestingly, the opposite effect occurred for individuals with decreased capacity for social pleasure. These findings suggest that social anhedonia may be a shared mechanism across autism and depression populations which may partially explain the experience of loneliness and prevalence of co-occurring mood disorders in ASD.

231 **186.231** Social Vulnerability and Mental Health in Adults with Autism Spectrum Conditions

S. Griffiths[1], *C. Allison*[2], *R. Kenny*[1], *R. Holt*[1] *and S. Baron-Cohen*[2], *(1)University of Cambridge, Cambridge, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom*

Background: Individuals with autism are at greater risk of developing co-morbid mental health conditions such as anxiety and depression. Social vulnerability may contribute to environmental risk for mental health conditions, by increasing the incidence of experiences such as bullying, domestic abuse, financial hardship, unemployment and difficulties accessing services. It is important to have measures of social vulnerability in order to look at whether this is a contributing factor in the high rates of mental health comorbidities in autism.
Objectives: To create a checklist to measure lifetime social vulnerability and compare responses in a large sample of adults with and without autism.

Methods: A new 'autism vulnerability checklist' was designed using a participatory research method. Items were developed from focus groups with stakeholders. Participants report whether they have experienced any of 60 events in 10 different domains (education, employment, finances, social service contact, criminal justice system contact, childhood victimisation, adulthood victimisation, domestic abuse, mental illness and social support). Adults with and without autism completed the checklist in an online survey. Participants also completed a demographics questionnaire, screening measures for anxiety and depression and a life-satisfaction scale. For each domain, participants' responses were coded according to whether they reported at least one experience, or no experiences. The number of different domains (0-10) endorsed as having at least one experience was calculated. Chi-squared tests for each domain were applied to compare the proportions of participants in each group who had experienced at least one event. T-test were used to compare average number of domains and scores on anxiety, depression and a life-satisfaction measures.

Results: Complete responses were collected from 435 autistic adults (58% female, age M = 43 years sd = 14.60) and 286 controls (73% female, age M = 51 years, sd = 15.47). Across all domains, significantly more autistic adults had experienced at least one event (X^2s > 18.78, ps < .001). The largest difference was for vulnerability in work ($X^2(1)$ = 111.28, OR= 10.01 95% CI = 6.21-16.15). Participants with autism had experienced events across a larger number of domains than controls (autism M = 7, control M = 5, $t(463.81)$ = 14.44, p < .001). They also reported higher rates of anxiety (autism M = 9.45, control M = 6.65, $t(680.59)$ = 11.40, p < .001) and depression symptoms (autism M = 11.52, control M = 6.00, $t(688.93)$ = 11.38, p < .001) and lower levels of life satisfaction (autism M = 13.56, control M = 19.02, $t(633.17)$= 11.43, p < .001) than controls.

Conclusions: Adults with autism are vulnerable to experiencing negative life events across a variety of domains including; education, employment, financial difficulties, social service contact, criminal justice system contact, childhood victimisation, adulthood victimisation, domestic abuse, mental illness and poor social support. These data also confirmed previous findings that adults with autism have high rates of symptoms of anxiety and depression and lower levels of life satisfaction. Future analysis will determine if social vulnerability is associated with mental health symptoms and life satisfaction in this population.

232 **186.232** Suicidal Ideation and Behaviors in Children, Youth, and Young Adults with Autism Spectrum Disorder (ASD): Rates & Outcomes Based on Parent-Report of 996 Individuals with ASD

B. L. Baer[1], *J. K. Law*[2,3,4], *L. Kalb*[5], *R. A. Vasa*[5,6], *H. C. Wilcox*[3,4] *and* ***P. H. Lipkin***[2,3,4], *(1)Interactive Autism Network, Baltimore, MD, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Johns Hopkins University School of Medicine, Baltimore, MD, (4)Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD, (5)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (6)Kennedy Krieger Institute, Baltimore, MD*

Background: Individuals with autism spectrum disorder (ASD) have a higher risk of mental health conditions than individuals without ASD. Recently, there have been growing concerns that individuals with ASD may also have an elevated risk of suicidal thoughts and behaviors, however little is known on this topic, especially in relation to children and adolescents.
Objectives: To determine the rates of suicidal ideation and behaviors in children, youth, and young adults with ASD.

Methods: 996 parent participants in the Interactive Autism Network (IAN)— a large, validated and verified, internet-mediated research registry— completed the Mental Health and Suicidal Behaviors Questionnaire (MHSBQ). The MHSBQ is a proxy-report questionnaire, for parents of verbal children and dependent young adults (≤25) with ASD, which collects information regarding comorbid mental health conditions, medications, service use, family history, and history of suicidal thoughts and behaviors.

Results: The rates of suicidal ideation and behaviors for children and young adults with ASD were reported at higher rates than their typically-developing siblings and the general population. 9.1% of parents reported that their child had a plan or tried to end his or her life. Additionally, 11.5% of parents reported that their child expressed active ideation, or thoughts of wanting to end his/her life (without acting on it), and an additional 21.0% expressed only passive ideation, or thoughts of wanting to die. Significantly higher rates of many comorbid mental health conditions were reported for individuals who experienced suicidal ideation or behaviors, compared to those who did not. Notable conditions include ADHD, anxiety, PTSD, and mood disorders (all $p<0.001$). Likewise, individuals who experienced suicidal ideation or behaviors (grouped together) were prescribed a significantly greater mean number of behavioral medications than those who did not experience any ideation or behaviors, $p<0.001$. There were also increases in lifetime service use for treating "emotional, behavioral, or mood related problems," as individuals progressed from passive ideation, to active ideation, or to plans or attempts, with statistically significant differences in service use between those who experienced ideation or behaviors, and those who did not ($p<0.001$). 8 years or younger was the most commonly reported age of onset for both passive ideation (28.7%), and active ideation (33.9%). Parents whose children tried to end their lives reported the onset of these suicidal behaviors as young as 5, ranging to 19 years old. Of those who tried to end their lives (n=35), 68.6% only tried one time, whereas nearly a third tried twice or more. The reported methods included suffocation (42.9%), poison (28.6%), motor vehicle accidents (20.0%), cuts/stabs (14.3%), falls/jumps (8.6%), and electrocution (5.7%).

Conclusions: Nearly half of those surveyed reported that their child or young adult with ASD had experienced suicidal ideation or behaviors, which indicates an alarmingly high potential for loss of life among this population. Since these behaviors are significantly coupled with comorbid mental health conditions and service use, this study points to the need for more available screenings and mental health services for children, youth, and young adults with ASD.

233 **186.233** The Link between Focused Attention and Emotion Regulation Ability in Children with ASD

A. P. Costa[1]*, C. Couronne*[2] *and G. Steffgen*[3]*, (1)University of Luxembourg, Esch sur Alzette, LUXEMBOURG, (2)University of Utrecht, Utrecht, Netherlands, (3)Institute for Health and Behaviour, University of Luxembourg, Luxembourg, Luxembourg*

Background: Empirical studies have frequently highlighted the importance of attentional mechanisms in the emotion regulation of people with autism spectrum disorder (ASD). For instance, people with ASD present distinct gaze patterns when looking at emotional stimuli. However, far less research has focused on the link between general attentional capacity and the ability to regulate emotions in people with ASD. In the typically developing (TD) literature it is shown that children's focused and sustained attention to non-emotional stimuli is related to a better regulation of negative emotions. Therefore, studying this link in ASD can help understand emotional difficulties in children with ASD.
Objectives: The present study aims to analyse the link between sustained attention to non-emotional stimuli and the use of emotion regulation strategies during a frustration-eliciting situation in children with ASD.

Methods: Thirty-seven children previously diagnosed with ASD (5 female) and 41 TD children (9 female) aged 3 to 13 years old participated in the study. Children first took part in a sustained attention task in which they watched a 3-minute slide presentation of 15 pictures of landscapes, animals, and humans. Then, children took part in a frustration-eliciting situation during which they were presented with attractive toys. After 15 seconds playing with the toys those were removed and placed behind a transparent barrier. Both tasks were videotaped and children's behaviors were coded by two independent observers. In the sustained attention task children were coded regarding the intensity of facial interest (0=not interested, 1=interested, 2=very interested) and the total amount of time in seconds looking at the slide presentation (maximum = 180 seconds). In the frustration-eliciting situation children's behaviors were coded into 12 categories and then grouped into 3 emotion regulation strategies: disruptive behavior (physical objection, crying/venting, defending, infraction, and verbal objection), passive tolerance (staring, doing nothing, self-distraction, and parent/researcher), and active self-regulation (directing situation, alternating activity, and complying).

Results: Regarding attention, children with ASD displayed less interest in the slide presentation [$t(70)=4.118$, $p<.001$, $d=0.96$] and watched the presentation for less time [$t(43)=5.492$, $p<.001$, $d=1.33$] than TD children. Regarding the use of emotion regulation strategies, a significant effect of group was found [$\Lambda=.71$, $F(3,74)=10.26$, $p<.001$, =.29]. Separate univariate ANOVAs revealed that children with ASD used more disruptive behaviors [$F(1,76)=25.24$, $p<.001$, =.25] and less passive tolerance behaviors [$F(1,76)=11.35$, $p<.01$, =.13] than TD children but did not differ regarding active self-regulation behaviors [$F(1,76)=2.03$, $p=.16$, =.03]. Regression analyses revealed that children's total duration of look but not the interest during the attention task significantly predicted children's use of disruptive behavior ($\beta=-1.12$, $p<.01$) and passive tolerance ($\beta=1.26$, $p<.01$) above and beyond ASD diagnosis.

Conclusions: Our results show a significant association between children's capacity for sustained attention and their use of less disruptive behaviors and more passive tolerance behaviors as emotion regulation strategies. However, mutual influences between sustained attention and emotion regulation can occur and should be taken into consideration when interpreting the results. The present results offer new perspectives on intervention programs for children with ASD with emotional difficulties.

234 **186.234** The Relationship between Autism and Depression and the Influence of Worry and Mastery: A Network Analysis

B. F. van Heijst[1]*, M. K. Deserno*[2]*, H. C. Comijs*[3] *and H. M. Geurts*[1]*, (1)University of Amsterdam, Amsterdam, Netherlands, (2)Department of Psychology, University of Amsterdam, Amsterdam, Netherlands, (3)VUMC, GGZ InGeest, Amsterdam, Netherlands*

Background: Autism and depression often co-occur: older adults with a history of depression report more autism symptoms than those without a history of depression, and depression is a common comorbidity for people with autism. Why do we see these two constructs covary so often? Do they influence each other directly, or is there another factor that explains their co-occurrence? Based on the depression literature we hypothesize that both worry and mastery (perceived control over life's stressors) will be of importance when trying to understand the relationship between depression and autism.
Objectives: To better understand the interrelatedness of autism and depression characteristics by investigating mastery and worry as potential bridges between autism and depression in a so called symptomatic network were the interaction between all symptoms are taken into account.

Methods: In study 1 adults with and without a previous diagnosis of depression (N= 375, age 60-90) took part. In study 2 adults with and without a previous diagnosis of autism (N= 202, age 31-89) participated. In both studies, self-report questionnaire data was collected on autism symptoms (AQ-28), depression symptoms (IDS-SR and SCL90 depression subscale, respectively), worry (Worry Scale-R) and mastery (The Pearlin Mastery Scale). A novel network approach, in which symptom interactions are taken into account, was used to create two concentration networks and the accompanying centrality indices.

Results: In the network for Study 1 we see one direct connection between autism (switching) and depression (motivation) characteristics, all other connections go through either mastery or worry nodes. Mastery has the greatest number of ties to other nodes, and the autism specific aspect of switching acts as a bridge between depression and all other autism characteristics. Worry is connected to mastery, depression and autism characteristics. The results of Study 2 differ from Study 1 in that all connections from autism to depression and worry go through mastery, i.e. mastery acts as a bridge. In addition, centrality indices show that mastery is the most central node in this network. In this network worry is no longer connected to autism.

Conclusions: In both studies mastery is an important factor between depression and autism, however it is especially important in the study with participants with autism. This suggests that when someone's toolbox (e.g., coping mechanisms, making use of their social network) to handle perceived stressors is expanded, this could have a positive impact on their sense of mastery and, in return, decrease the risk of developing depressive symptoms.

235 **186.235** The Relationship between Group Belonging, Subclinical Autistic Traits and Suicidal Ideation

K. Monaghan[1] *and A. E. Robertson*[2]*, (1)University of Dundee, Dundee, United Kingdom, (2)Coventry University, Coventry, United Kingdom*

Background:

The prevalence of suicidal ideation in individuals with Asperger syndrome (AS) is estimated to be nine times higher than in the general population (Cassidy et al., 2014). Individuals with AS and Autism Spectrum Conditions (ASC) share behavioural characteristics (autistic traits), which generate difficulties in social integration (Jobe & White, 2006). There is evidence that suicidality and autistic traits are related, and that 'thwarted belongingness' is a key component (Cassidy & Pelton, 2017). In the general population, group identification (the *subjective* feeling of belonging to a group) is a protective factor for mental distress (Sani et al., 2012). However, it is unknown whether autistic traits are related to group identification, and how both of these factors might be associated with suicidal ideation.

Objectives:

H1 – There will be a significant negative relationship between autistic traits and group identification

H2 – Autistic traits and group identification will both significantly predict suicidal ideation

Open-ended questions – The aim was to determine whether there was a difference between any interpersonal stressors reported by those with high and low levels of autistic traits.

Methods:

The Autistic Spectrum Quotient (AQ; Baron-Cohen et al., 2001), Group Identification Scale (GIS: Sani et al., 2015), Beck Scale for Suicide Ideation (BSSI; Beck, Kovacs & Weissman, 1979) were administered to 108 individuals. AQ scores ranged from 4 to 42 (M = 16.68; SD = 8.28). The sample was split at the median, and therefore those with a score of 17 or more were classed as belonging to the 'high' AQ group, with the remainder belonging to the 'low' AQ group. Mean group identification scores ranged from 4 to 27 (M = 19.10; SD = 4.96).

Four open-ended questions were presented to participants. They explored each individual's: i) major life stressors, ii) methods of coping, iii) self-awareness of support required, and iv) knowledge about autism spectrum conditions and experiences of distress.

Results:

BSSI: The overall model demonstrated that gender, autistic traits and group identification statistically significantly predicted suicidal ideation, *F(3,104) = 9.809, p < .001, R2 Adj. = .198*

Open-Ended Questions: A content analysis indicated that those within the high AQ group reported more interpersonal stressors, more self-harm and substance misuse and less socially supported coping methods than those in the low AQ group.

Conclusions:

Autistic traits and group belonging significantly predict suicidal ideation in adults in the general population. Based on the results from this study, we suggest that research should explore the subjective dimension of social integration in ASC, in order to help further our understanding of suicidal thoughts in this population. There is evidence that positive identification with the autistic community is associated with positive mental health outcomes (Cooper et al., 2017), and we suggest that future research also consider other groups.

236 **186.236** Visual Perceptual Correlates of Autistic Traits in Fragile X Syndrome

J. Glennon[1]*, L. Mason*[2]*, H. D'Souza*[2]*, A. Karmiloff-Smith*[2] *and M. S. Thomas*[2]*, (1)Birkbeck, University of London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom*

Background: Approximately one third of individuals with fragile X syndrome (FXS) reach clinical thresholds for autism, making it the leading known monogenic cause of autism and intellectual disability. Recently, it has been gathering momentum as a useful model for studying the emergence of early autism risk factors when genetic aetiology is constrained. Yet little is known about the nature of this syndromic form of autism. Attentional disengagement difficulties, proposedly due to a featural processing bias, and superior visual search performance, commonly attributed to enhanced perceptual discrimination, are well documented in idiopathic or non-syndromic autism. Critically, it remains unclear whether autism in FXS is associated with this same visuo-perceptual profile.

Objectives: We explore the visuo-perceptual correlates of autistic traits in children with FXS, in the expectation that higher levels of these traits will be associated with delayed attentional disengagement above and beyond the effects of intellectual ability. Conversely, we do not expect an association between autistic traits and visual search performance.

Methods: We apply eye tracking paradigms widely used in the autism literature to document visual search and attentional disengagement performance in children with FXS aged between 6 and 10 years. Autism traits are measured using the Social Responsiveness Scale, second edition. Between-groups cross-sectional trajectory analyses are run, incorporating data from children with non-syndromic autism (n=15) and typically developing controls (n=52) matched on chronological age and intellectual ability.

Results: Autistic traits in FXS are driven by unique visuo-perceptual underpinnings relative to children with non-syndromic autism and typically developing controls.

Conclusions: Our findings serve to illuminate the complex heterogeneity associated with both neurodevelopmental disorders, with clinical implications regarding the application of autism intervention programmes to children with FXS.

237 **186.237** 'Something Needs to Change': Mental Health in Young Autistic Adults

L. Crane[1]*, F. Adams*[2]*, G. Harper*[2]*, J. Welch*[2] *and E. Pellicano*[3]*, (1)Centre for Research in Autism and Education, UCL Institute of Education, University College London, London, United Kingdom, (2)Ambitious about Autism, London, United Kingdom, (3)Macquarie University, Sydney, Australia*

Background: Given that rates of mental health problems are disproportionately high in young people generally, and that young adults display poor help-seeking behaviours, there is an urgent need to explore mental health in young autistic adults, who may be an especially vulnerable group. Indeed, the transition from childhood to adulthood is a challenging time for young autistic people in general, with high rates of bullying and victimisation, as well as low rates of post-secondary education, employment, social participation and quality of life. Particularly worrying is that even autistic adults with "good" outcomes (e.g., higher rates of employment, marriage/partnership, and independent living) show strikingly high rates of co-occurring mental health conditions.

Objectives: The aims of the current research were to: (1) investigate young autistic people's views and experiences of mental health problems and services; and (2) identify possible ways of supporting young autistic people who are experiencing poor mental health. These aims were achieved through the use of a community-based participatory research (CBPR) approach. CBPR involves a partnership between, for example, community members and academic researchers, in which different types of expertise are valued equally, and ownership of the research is shared. In this research, a group of young autistic people from an autism charity developed a research project in collaboration with a team of academic researchers.

Methods: In total, 130 young autistic adults between the ages of 16 and 25 years took part in the research: 109 young people (M age = 20.57 years; 33 male, 56 female, 17 non-binary, 3 did not disclose) completed an online survey and 21 young people (M age = 20.90 years; 9 male, 10 female, 2 non-binary) took part in in-depth interviews. Data were collected, analysed and interpreted by the researchers and young autistic people, in partnership.

Results: Consistent with previous research, high rates of mental health problems (80.7%) were found among our sample of young autistic adults. Yet these young people reported feeling unhappy and depressed, worthless, under strain, unable to overcome their difficulties, unable to face up to problems, and lacking in confidence generally – irrespective of whether they were experiencing mental health problems. As such, they reported finding it difficult to recognise the signs and symptoms of poor mental health. More worryingly, when the young people identified that they needed support for their mental health problems, they reported high levels of prejudice and discrimination, and encountered severe obstacles (e.g., lack of available services, delays, services not tailored to their needs).

Conclusions: Young autistic people are already potentially at a disadvantage simply because society does not understand what it is like to be autistic. This research clearly suggests that young autistic people may be doubly disadvantaged due to the mental health challenges that confront them. The results have implications for improving clinical services, including: (1) more initiatives to reduce stigma associated with autism and mental health; (2) increased training for professionals; and (3) greater autistic involvement in the design and delivery of services that directly affect them.

238 **186.238** Heightened Neural Processing of Errors Uniquely Relates to Social Anxiety Symptoms in Youth with ASD

T. Rosen[1] *and M. D. Lerner*[2]*, (1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background: Individuals with autism spectrum disorder (ASD) often experience symptoms associated with generalized anxiety disorder (GAD), obsessive-compulsive disorder (OCD), and social anxiety disorder (SA; Hallett et al., 2013). In other populations, these symptoms are associated with a larger error-related negativity (ERN; Weinberg, Riesel, & Hajcak, 2012), an event-related potential in the scalp-derived electroencephalogram (EEG) that indexes endogenous threat sensitivity (Weinberg, Riesel, & Hajcak, 2012). As such, the ERN may relate to the clinical presentation of anxiety in ASD. However, studies examining these associations in youth with ASD have yielded mixed results (see Hüpen, Groen, Gaastra, Tucha, & Tucha, 2016). This may be due to a focus on broad measures of anxiety, rather than specific symptoms associated with the ERN. In addition, factors known to affect ERN magnitude, such as depression, age, and verbal abilities (Henderson et al., 2006; Meyer, Weinberg, Klein, & Hajcak, 2012), are rarely modeled in this literature.
Objectives: Therefore, the present study aimed to extend this literature by clarifying the relationship between the ERN and anxiety in ASD. This was achieved by examining the relation of the ERN to *specific* anxiety symptoms, as well as relevant demographic and clinical variables that could affect this relationship, among youth with ASD.

Methods: Fifty-one youth (38 males), ages 8-17 (M_{age} = 12.15, SD_{age} = 2.94) with Autism Diagnostic Observation Schedule – 2 (ADOS-2; Lord et al., 2012) confirmed ASD diagnoses and FSIQ ≥ 70 (per the Kaufman Brief Intelligence Test-2; Kaufman & Kaufman, 2004) completed a modified Flanker task, from which the ERN component was obtained (see Figure 1). Parents and children reported on anxiety, depression, and ASD symptoms (see Table 1).

Results: Of the anxiety scales examined, the $\mathrm{ERN}_{\mathrm{Res}}$ only correlated with self-reported SA symptoms (see Table 1). The relation between SA symptoms and the $\mathrm{ERN}_{\mathrm{Res}}$ was evident for the SA performance fears subscale, and not the SA humiliation rejection fears subscale. The relation between performance fears and the $\mathrm{ERN}_{\mathrm{Res}}$ was robust to controlling for self-reported depression symptoms, parent-reported ASD symptoms, verbal IQ, and age in a hierarchical regression, with a medium effect (B = -.26, p < .01).

Conclusions: Self-reported performance fears related to a larger $\mathrm{ERN}_{\mathrm{res}}$; this relation was robust to controlling for age, verbal IQ, depression, and ASD symptoms. Findings suggest that heightened threat sensitivity may be representative of the ambiguous SA presentation in ASD, characterized by social fearfulness and discomfort *without* fear of negative evaluation (Kerns, Kendall, et al., 2016). Interestingly, no associations were found between the $\mathrm{ERN}_{\mathrm{res}}$ and GAD or OCD symptoms. In some youth with ASD, obsessive and compulsive behaviors are more closely related to restricted interests and repetitive behaviors (Spiker, Lin, Van Dyke, & Wood, 2012) rather than anxiety (Kerns et al., 2014), while GAD symptoms may more specifically relate to intense preoccupations (Kerns et al., 2016). Thus, self-reported OCD and GAD symptoms in youth with ASD may reflect a different etiopathology than that which drives the OCD- and GAD-ERN associations in typically developing individuals.

239 **186.239** Symptom Presentation of Children with Autism Spectrum Disorder after Maltreatment and Trauma

A. Barrett *and T. W. Vernon, University of California Santa Barbara, Santa Barbara, CA*

Background: Children with disabilities are 3.4 times more likely to be maltreated than nondisabled peers, with children diagnosed with Autism Spectrum Disorder (ASD) encompassing a significant proportion of these children (Sullivan & Knutson, 2000). Families with a child with ASD experience several maltreatment risk factors, including increased parental stress, limited social support, increased isolation, and financial burden. Although children with other disabilities may experience more frequent episodes of maltreatment, victims with ASD may go unidentified due to impairments in verbal communication and existing externalizing behaviors that may mask common red flags of trauma. Paradoxically, there are several characteristics of ASD that may exacerbate posttraumatic stress response in this population, such as pre-existing anxiety-related conditions and poor emotion regulation abilities. Despite this knowledge, very few studies have examined posttraumatic response in individuals with ASD and results are inconsistent.
Objectives: This study examined how children with ASD respond to trauma and maltreatment compared to typically developing children. It also explored similarities and differences in symptom presentation compared to children with ASD who have not experienced maltreatment or trauma.

Methods: Participants included a nationwide sample of parental guardians of children ages 3-12 years who are a) a victim of maltreatment or trauma, or b) have a diagnosis of autism spectrum disorder, which resulted in three participant groups: ASD trauma, TD trauma, ASD no trauma. Parents completed the Adverse Childhood Experiences Survey to assess for experiences of abuse, neglect, witnessing domestic violence, or trauma. Parents also completed the Trauma Symptom Checklist for Young Children to measure emotional-behavioral and posttraumatic stress symptoms, the Social Responsiveness Scale to measure autism-related symptoms, and items of the Repetitive Behavior Scale to measure for self-injurious, compulsive, and ritualistic behaviors. Two-way MANOVAs were conducted to assess for differences in symptom presentation between the three groups. Analyses included moderators to assess the impact of age, trauma type, and verbal ability on posttraumatic stress response.

Results: Data collection and data analysis are ongoing and will continue to identify significant group differences. Preliminary analyses suggest that children with ASD who have experienced trauma will demonstrate elevations in anxiety- and emotion dysregulation-related posttraumatic stress symptoms. Within this group, it is also predicted that victims with increased social cognition and social awareness will experience stronger posttraumatic stress symptoms than those with decreased social cognition and awareness. Lastly, preliminary data suggests that victimized ASD participants with lower age and reduced verbal abilities are suspected to demonstrate higher levels of externalizing symptoms compared to the victimized typically developing and non-victimized ASD groups.

Conclusions: To our knowledge, this study is the first study to compare posttraumatic stress response between children with autism and typically developing peers. It is hoped that these results will contribute to a gap in the literature regarding posttraumatic response in children with ASD. By understanding how this vulnerable population responds to maltreatment and traumatic experiences, psychologists and practitioners may be better equipped with the knowledge needed to identify victims and provide appropriate care.

240 **186.240** Exploring the Prevalence of Callous-Unemotional Traits in Young People with Autism and Their Association with Conduct Problems

*Y. Mahadevan[1], **W. Mandy**[2], A. McKenna[3], K. Stevenson[3], M. Bindman[3], M. Murin[4] and D. H. Skuse[5], (1)UCL, London, United Kingdom, (2)University College London, London, United Kingdom of Great Britain and Northern Ireland, (3)Great Ormond Street Hospital, London, United Kingdom, (4)Great Ormond Street Hospital for Children, London, United Kingdom of Great Britain and Northern Ireland, (5)Behavioural and Brain Sciences Unit, Population Policy and Practice Programme, UCL Great Ormond Street Institute of Child Health, University College London, London, United Kingdom*

Background:

Most autistic children and adolescents experience additional neurodevelopmental, behavioural and mental health difficulties, and these have a significant impact on their wellbeing and functioning. Identifying and understanding such co-occuring difficulties is therefore of the upmost importance. Conduct problems are common amongst autistic youths, but the mechanisms underlying these are not currently well understood, which limits efficacy of treatment. One possibility is that in some instances, conduct problems may reflect the presence of callous-unemotional (CU) traits, conceptualised as atypical emotional processing leading to indifference to the suffering of others. To date, only one study has explored the link between CU-traits and ASD, finding a positive correlation in an adolescent-only sample. However, the potential role played by CU traits in the development of conduct problems of autistic young people has not been investigated.

Objectives:

To use gold-standard measures to investigate: (1) the prevalence of CU traits amongst a clinical population of autistic children and adolescents; and (2) the association between CU traits and conduct problems in autistic young people.

Methods:

Participants were 80 children and adolescents meeting diagnostic criteria for autism spectrum disorder who had IQs in the normal range. Autistic symptoms were measured using the Developmental, Dimensional and Diagnostic Interview (3Di) and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-II). IQ was measured using Wechsler Scales. CU-traits were quantified with parent and teacher versions of the Inventory of Callous-Unemotional Traits. Conduct problems were assessed using DSM checklists, and the Strengths and Difficulties Questionnaire.

Results:

In this sample of autistic children and adolescents, CU-traits scores were common, normally distributed and unrelated to autism symptom severity and IQ. They were strongly and significantly predictive of oppositional behaviours and emotional dysregulation. In addition they were significantly associated with more severe conduct problems indicative of a conduct disorder, including bullying, stealing and lying. These associations between CU-traits and conduct problems persisted when we controlled for autism symptom severity, IQ and symptoms of attention deficit/hyperactivity disorder.

Conclusions:

CU-traits appear to represent a key dimension of variability amongst autistic children and adolescents, and are highly predictive of conduct problems. Autistic young people, and especially those with co-occurring conduct problems, should be assessed for CU-traits in order to enhance clinical formulation.

241 **186.241** Autistic Features and Gender-Specific Eating Behavior throughout Childhood: The Generation R Study

***M. van 't Hof**[1,2,3,4], W. A. Ester[4,5], F. Serdarevic[2,6], M. Hillegers[7], H. Tiemeier[6,8,9], H. W. Hoek[10] and P. W. Jansen[6,11], (1)Erasmus MC-University Medical Center, Department of Child and Adolescent Psychiatry / Psychology, Rotterdam, Netherlands, (2)The Generation R Study Group, Erasmus University Medical Center, Rotterdam, Netherlands, (3)Sarr Expert Centre for Autism, Lucertis Child- & Adolecent Psychiatry, Rotterdam, Netherlands, (4)Parnassia Psychiatric Institute, The Hague, Netherlands, (5)Sarr Expert Centre for Autism, Lucertis Child- & Adolecent Psychiatry, Rotterdam, Netherlands, Rotterdam, Netherlands, (6)Department of Child and Adolescent Psychiatry / Psychology, Erasmus MC-University Medical Center, Rotterdam, Netherlands, (7)Department of Child and Adolescent Psychiatry / Psychology, rasmus MC-University Medical Center, Rotterdam, Netherlands, (8)Department of Epidemiology, Erasmus MC-University Medical Center, Rotterdam, Netherlands, (9)Department of Psychiatry, Erasmus MC-University Medical Center, Rotterdam, Netherlands, (10)Department of Psychiatry, University of Groningen - University Medical Center Groningen, Groningen, Netherlands, (11)Department of Psychology, Education and Child Studies, Erasmus University Rotterdam, Rotterdam, Netherlands*

Background: Children with autism often exhibit problematic eating behaviors. It is unclear whether this relation is also present among children with non-clinical autistic features, whether this is a prospective relationship and whether any gender differences are present.
Objectives: To investigate the relationship between autistic features and eating behavior throughout childhood and their sex-specificity, in a general population sample.

Methods: This study was embedded in Generation R, a prospective population-based cohort study from fetal life onwards. Children born in Rotterdam between April 2002 and January 2006 were followed up until age ten years. We included 4413 mother-child dyads with cross-sectional information on autistic features and eating behavior at age of three/four years. For 3559 mother-child dyads, prospective information was available on autistic traits at age six and eating behavior at age ten years. We collected parental reports of Pervasive Developmental Problems at age three and autistic traits at age six years. Eating behavior was assessed at ages four and ten years.

Results: Cross-sectional analyses showed that maternal reported Pervasive Developmental Problems score of preschool children was positively associated with Satiety Responsiveness, Food Fussiness, Emotional Undereating, Emotional Overeating and Food Responsiveness, and negatively with Enjoyment of Food (e.g. per 1 SD Pervasive Developmental Problems score, adjusted B for Food Fussiness SD-score = 0.12; 95% CI, 0.09 to 0.15). Prospective analysis showed that autistic traits at six years were positively associated with Picky Eating and Food Responsiveness at age ten years in both boys and girls (e.g. B for Picky Eating = 0.05; 95% CI, 0.01 to 0.09), and with Emotional Undereating (B = 0.10; 95% CI, 0.02 to 0.17) and Emotional Overeating (B = 0.16; 95% CI, 0.08 to 0.23) in girls only.

Conclusions: Preschool autistic features were associated with eating behavior problems in early and middle childhood, with results pointing to a gender-specific presentation. This suggests that eating behavior problems need more attention in the diagnostics of autism, particularly in girls.

1:45 PM - 2:35 PM - Grote Zaal

1:45 **188.001** Modular Approach to Supporting Students with ASD in Classrooms: Feasibility and Preliminary Efficacy of the Saage Intervention

__S. Iadarola__[1], B. Cavanaugh[1], K. Fontechia[2], R. Haynes[3], L. Levato[1], R. J. Martin[4], L. A. Oakes[1], C. M. Anderson[4], R. Iovannone[2] and T. Smith[5], (1)University of Rochester Medical Center, Rochester, NY, (2)University of South Florida, Tampa, FL, (3)Southern Illinois University, Carbondale, IL, (4)May Institute, Randolph, MA, (5)University of Rochester, Rochester, NY

Background: Although behavioral strategies have been shown to be useful for teaching new skills to children with autism spectrum disorder (ASD), they are seldom implemented in public schools (Kasari & Smith, 2013). Barriers include low buy-in, inadequate training, and resource limitations that lead to poor fidelity. However, increases in teacher fidelity and improvements in children's classroom behavior have been reported when interventions involve collaboration between school teams and ASD specialists for setting goals, adapting strategies, and providing in-vivo coaching (Iadarola et al., 2017). We incorporated these features into a framework, Students with Autism Accessing General Education (SAAGE), which aims to promote the success of students with ASD in classrooms and reduce potential barriers to less restrictive environments. Consistent with interventions that have been successful with other populations, SAAGE is organized into "modules" that address core and associated features of ASD. Each module comprises a small, targeted set of empirically supported behavioral strategies directed at a particular problem, with decision rules or assessment procedures for selecting which modules to implement and under what circumstances. SAAGE implementation is guided by a coach who assists the school team to assess student needs, identify student goals, select relevant modules, and receive in-vivo guidance on module implementation.
Objectives: Pilot SAAGE and evaluate (1) feasibility (i.e., recruitment/retention, fidelity, buy-in) and (2) preliminary outcomes.

Methods: We conducted a quasi-experimental design across three sites, participants were 14 students (12 boys, 2 girls) with ASD, *M(SD)* age = 9.45(2.42) years and 14 teachers. Research personnel served as coaches. Coach-teacher dyads engaged in a systematic process of (1) selecting goals and modules based on student and classroom needs, (2) participating in up to 12 hours of in-vivo coaching per module, (3) evaluating student progress and intervention buy-in. To measure student progress, an independent evaluator administered the Teacher-Nominated Target Behaviors (TNTB) interview and an observation based on the Global Assessment Scale (GAS). Buy-in was assessed from the 29-item Usage Rating Profile (URP), rated from 1 (strongly disagree) to 6 (strongly agree), and a 10-item scale of coaching quality, rated from 0 (lowest quality) to 4 (highest quality).

Results: Teacher Fidelity: Across 51 observations by study personnel, teacher adherence to intervention procedures averaged 93% (8.2%), and quality of implementation averaged 99% (4.8%). Buy-in: On the URP, teachers highly rated SAAGE acceptability, *M(SD)* = 5.22(.31), usability, *M(SD)* = 5.61(.10), and feasibility, *M(SD)* = 5.47(.27). The mean rating of coaching quality was 3.84(.07). Student Outcomes: On the TNTB, teachers rated 11 of 14 students as "much improved" or "very much improved" on at least one target behavior; 8 were rated as "much" or "very much improved" on all three target behaviors. On the GAS, the percentage of students who demonstrated improvement was 38% at midpoint 1 and 50% at midpoint 2.

Conclusions: SAAGE was implemented with high fidelity, and educators rated the process positively. Preliminary outcome data for the students are encouraging. These results indicate that modular interventions with in-vivo coaching may be a promising approach for schools to effectively support students with ASD.

1:57 **188.002** A School-Based Sensory Intervention for Food Selectivity in Young Autistic Pupils

__J. Galpin__[1], L. Osman[2] and C. Paramore[3], (1)The Bridge London Trust, London, United Kingdom, (2)The Bridge School, London, London, United Kingdom, (3)Nutrition and Dietetics, The Whittington Hospital NHS Trust, London, United Kingdom

Background: Feeding difficulties are twice as prevalent in autistic children as in neurotypical children. Food selectivity is the most common feeding difficulty in this population and has a significant association with disruptive mealtime behaviour. There is also strong correlation between mealtime behaviour and parental stress. Furthermore, parents of autistic children identify diet as a priority area for support. A limited diet has a

negative impact upon nutritional intake, cognitive development and overall health. The need for food selectivity interventions to address the sensory components of eating is underlined by the increasing evidence supporting the causal relationship between sensory differences and food selectivity.
Objectives: To aim of the study, produced by school-based professionals, was to examine the impact of a sensory based intervention to address food selectivity in autistic pupils that could be integrated into the school day and delivered by existing staff in the school setting.

Methods: 19 children (3 girls and 16 boys) from the same government-funded, special school in inner-city London took part. Participants ranged in age from 4 years 10 months to 10 years 7 months (*M*=6 years; 5 months; *SD*=1;7). The intervention focused on encouraging tactile and oral exploration of foods, looking to normalise sensation, as the first of a sequence of steps to address food selectivity. It was delivered daily over 12 weeks by existing school staff following a brief training session. 30% of sessions were observed by the school dietitian to ensure fidelity to the intervention. Baseline and Post intervention measures were taken in terms of: number of foods eaten across 17 categories (based on food group and texture); and scores on the Brief Autism Mealtime Behaviour Inventory (BAMBI).

Results: There was a significant difference between the number of food categories eaten following the intervention ($F(1,36)=10.46$, $p=.003$, $\eta^2=.23$). The average number of categories before the intervention (*M*=5.53, *SD*=3.64) was significantly lower than post intervention (*M*=9.26, *SD*=3.48). Total BAMBI scores of the participants were significantly lower post-intervention (*M*=31.00, *SD*=9.37) than at baseline (*M*=38.53, *SD*=12.49), $t(18)=4.66$, $p<.001$, $d=1.07$. Similarly, the Food Selectivity score was significantly lower post-intervention (*M*=11.37, *SD*=4.31) than at baseline (*M*=14.00, *SD*=4.67), $t(18)=5.06$, $p<.001$, $d=1.16$. Food Refusal scores were also significantly lower on average post-intervention (*M*=5.53, *SD*=2.04) than at baseline (*M*=7.26, *SD*=2.85), $t(18)=3.18$, $p=.005$, $d=0.73$. Disruptive Mealtime Behaviour scores were also significantly lower post-intervention (*Mdn* = 7, range: 5-14) than at baseline (*Mdn* = 10, range: 5-21), $Z=-2.46$, $p<.05$, $r=-0.4$.

Conclusions: The results from the study are promising and indicate that sensory-based intervention can successfully reduce selective eating in primary school aged autistic pupils. Furthermore, it demonstrated that school staff can deliver the programme to fit in with the existing school day, with little disruption and few financial, time or staff resources required. The lesson plans developed for the study could therefore be easily adopted by more schools to support selective eating. Further research is needed to see if the method can be extended to main meals and the results generalised to a home setting.

2:09 **188.003** Efficacy of a School-Based Treatment Model for Adolescents with Autism: Effects on School Quality

S. Odom[1], *K. Hume*[1], *L. E. Smith DaWalt*[2], *B. Kraemer*[3] *and L. J. Hall*[3], *(1)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)University of Wisconsin-Madison Waisman Center, Madison, WI, (3)Special Education, San Diego State University, San Diego, CA*

Background: The increased prevalence of autism spectrum disorder (ASD) has created a demand for efficacious treatment services for children and youth with ASD, and one context in which most participate is the public schools. While much research has been conducted on comprehensive treatment models (CTM) for preschool and early school age children with ASD, few programs have been developed and evaluated for adolescents with ASD. This has created a gap in the field between needed effective services and treatment approaches that are evidence-based.
Objectives: The purpose of this study was to examine the efficacy of a comprehensive treatment model designed to improve the quality of educational programs for adolescents with ASD attending high school.

Methods: The Center for Secondary Education for Students with ASD (CSESA) designed a CTM for high school students with ASD that consisted for four program features: Academics, Independence, Social Competence, and Transition/Families. After training on the model, an "autism team" at the school implemented the program over a two year period. A primary feature of the CSESA model was to improve the overall quality of the program, which would serve as the foundation for the four features of the CSESA model. The Autism Program Environment Rating Scale (APERS) was the primary measure used to assess program quality. The APERS is a 66-item, five-point Likert-type scale that provides a total quality rating score and also four composite scores that reflect the quality of program features noted previously.
Design: Following a randomized clinical trial design, sixty high schools located in North Carolina, California, and Wisconsin were randomly assigned to the CSESA and a Services as Usual (SAU) condition. A total of 546 high school students with ASD participated in the study. The APERS was administered at the beginning of the school year and again at the end of the subsequent school year (~18-20 months later), with CSESA schools implementing the CTM and SAU schools following the practices they typically employed.
Results:

Examinations of reliability yielded Cronbach alpha scores of .94 for the total rating and an average of .76 for domain scores. Inter-observer agreement, collected on 20% of the sample, was 85% for agreement within one point and 76% for exact agreement. An ANCOVA was used to create adjusted posttest means, with the pretest as the control, for the two groups. The total mean item rating (d=.99) and the four composite scores [academic (d=.71), social (d=1.32), independence (d=.69), and transition/families (d=.83)] were significant at the p> .05 level (with Bonferonni adjustment), with mean rating favoring the CSESA group (see figure below).

Conclusions: This study demonstrated the efficacy of the CSESA model for improving the quality of the program environment for high school students with ASD. The next steps in this research will be to examine the relationship of program quality to the fidelity with which program features and evidence-based practices are implemented and the impact on the adolescents with ASD.

2:21 **188.004** Does Peer-Mediation Increase Effectiveness of the PEERS Curriculum? A Pilot Randomized Control Trial Examining Social Function, Well-Being and Classroom Social Network Centrality

N. L. Matthews[1], *E. Rotheram-Fuller*[2], *B. Orr*[1], *K. Warriner*[3], *M. DeCarlo*[1], *M. Sorensen*[1], *J. Laflin*[1] *and C. J. Smith*[4], *(1)Southwest Autism Research and Resource Center, Phoenix, AZ, (2)Arizona State University, Tempe, AZ, (3)Comprehensive Behavioral Programs, Southwest Autism Research and Resource Center, Phoenix, AZ, (4)Southwest Autism Research & Resource Center, Phoenix, AZ*

Background: PEERS (Laugeson & Frankel, 2010) is one of the most well-studied social skills interventions for intellectually-able adolescents with autism (ASD). However, the potential for increasing effectiveness using peer mediation strategies remains unexamined. Also, the majority of previous research has relied on questionnaires to the exclusion of more objective outcome measures (Hood et al., 2017).
Objectives: (1) To compare change in adolescent- and parent-reported social functioning and well-being from pre-to-post intervention and at a

4-month follow-up among participants who completed PEERS, a peer-mediated PEERS model (PMP), or a delayed treatment control (DTC) group. (2) To compare classroom social network centrality (SNC; Farmer & Rodkin, 1996) among study groups at immediate and 4-month follow-ups.

Methods: Participants were 34 intellectually able (IQ ≥ 70) adolescents with ASD randomly assigned to PEERS, PMP, or DTC (see Table 1); one parent of each adolescent; 16 typically developing peer mentors, and 562 general education (GE) classmates of participants with ASD. PEERS and PMP were administered identically except for the peer-mediation strategies of proximity and peer initiation (Odom & Strain, 1984) in PMP using a 1:1 ratio of typically developing peer mentors. Questionnaires were collected pre- and post-treatment, and at a 4-month follow-up. SNC data were collected post-treatment and at a 4-month follow-up in a subsample whose schools approved research procedures. Interviews were conducted with GE classmates in one classroom of each participant with ASD to generate SNC scores (0-Isolated; 1-Peripheral; 2-Secondary; 3-Nuclear).

Results: Reported in Table 1, MANOVAs indicated greater improvement at immediate follow-up in parent-reported social skills and problem behaviors, adolescent-reported social skills knowledge, and loneliness in PMP relative to DTC. PEERS participants demonstrated greater improvements in adolescent-reported social skills knowledge, loneliness, and hosted get-togethers relative to DTC. Improvements in social skills, problem behaviors, and social skills knowledge were maintained by PMP at the 4-month follow-up, as were improvements in social skills knowledge and adolescent-reported get-togethers by PEERS participants. Notably, number of actual get-togethers did not differ between PEERS and PMP at either follow-up. Table 2 reports SNC scores. When PEERS and PMP were collapsed into one treatment group, Fisher's exact tests indicated significantly less isolation in treatment participants relative to DTC at the immediate follow-up (p = .05), but not at the 4-month follow-up (p = 0.56).

Conclusions: Findings suggest a modest improvement parent-reported social skills and problem behaviors when PEERS was implemented using peer mediation strategies. When PEERS and PMP were collapsed into one treatment group, treatment participants were less isolated in their classrooms relative to DTC at the immediate follow-up, but these levels of engagement were not maintained. SNC findings provide initial evidence for generalization of acquired skills to the classroom that requires replication with a larger sample. Not a single participant with ASD received a nuclear rating, and very few were rated as secondary. This suggests the need for additional efforts to improve peer acceptance of high school students with ASD in GE classrooms. To our knowledge, this is the only study to examine SNC of PEERS graduates.

Oral Session - 11B
Interventions - Non-pharmacologic - School-Age, Adolescent, Adult
189 - Improving Employment Outcomes for Adults
2:40 PM - 3:30 PM - Grote Zaal

2:40 **189.001** Evaluation of the BOOST-a Transition Planning Program for Adolescents on the Autism Spectrum: Quasi-Randomised Controlled Trial and Process Evaluation

*M. Hatfield[1], **M. Falkmer**[2], T. Falkmer[3] and M. Ciccarelli[4], (1)Curtin University and Autism CRC, Perth, Australia, (2)School of Occupational Therapy and Social Work, Curtin University, Perth, Western Australia, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Australia, (4)Curtin University, Perth, Australia*

Background: The Better OutcOmes & Successful Transitions for Autism (BOOST-A^{TM}) is an online, autism-specific, transition planning program that prepares students for leaving school. The program was developed as the majority of existing transition planning programs are focused on people with a disability in general and may not meet the specific need of adolescents on the autism spectrum. In addition, there are methodological limitations to many of the studies determining their effectiveness.

Objectives: A quasi-randomized controlled trial was conducted to evaluate the effectiveness of BOOST-A^{TM} in enhancing self-determination. In addition, a process evaluation was conducted to determine the effectiveness, usability, and barriers and facilitators to using BOOST-A^{TM}.

Methods: Participants were adolescents on the autism spectrum enrolled in Years 8 to 11 in Australian schools (N=94). Participants were blinded to the trial hypothesis and were allocated to a control (n=45) or intervention (n=49) group. Over a 12 month period, the intervention group used BOOST-A^{TM} while the control group engaged in regular practice. The primary outcome was self-determination and secondary outcomes included career planning and exploration, quality of life, environment support, and domain specific self-determination. Data were collected from parents and adolescents. A process evaluation was conducted after the trial to allow adolescents on the autism spectrum (n=33) and their parents (n=39) from the intervention group to provide feedback via an online questionnaire. Of these, 13 participants were interviewed to gain further in-depth information about their experiences using BOOST-A^{TM}. Data were analysed using descriptive statistics and thematic analysis.

Results: No significant differences were found in overall self-determination between groups. Significant differences in favor of the intervention group were found in three areas: opportunity for self-determination at home (parent report); career exploration (parent and adolescent report); and transition-specific self-determination (parent report). Themes identified in the process evaluation found that the BOOST-A^{TM} encouraged participants to take action to overcome an inertia that accompanied their fear leaving school. It also supported the development of new insights about interests and strengths that led to clearer plans for the future. Adolescents described feeling empowered in the transition planning process as a result of the strengths-focus of BOOST-A^{TM}. Some participants did not find the program helpful; mainly because they did not have a champion to support them to take action in the transition planning process.

Conclusions: The findings provide preliminary evidence that BOOST-A^{TM} can enhance some career-readiness outcomes. Overall self-determination was not significantly greater in the intervention group and the process evaluation revealed why BOOST-A^{TM} was beneficial for some participants more than others.

2:52 **189.002** Evaluating the Effectiveness of an Autism-Specific Workplace Tool

***M. T. Scott**[1,2], M. Falkmer[3,4,5], T. Falkmer[2,6,7] and S. J. Girdler[2,8], (1)School of Occupational Therapy and Social Work, Curtin University, Perth, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)School of Occupational Therapy and Social Work, Curtin University, Perth, Western Australia, Australia, (4)School of Education and Communication, CHILD programme, Institute of Disability Research, Jönköping University, Jönköping, Jönköping County, Sweden, (5)Curtin University, Bentley, Australia, (6)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Australia, (7)Department for Rehabilitation, Jönköping University, Jönköping, Sweden, (8)School of*

Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia

Background: Employment is a highly desirable social achievement for most individuals, including those on the autism spectrum. Work facilitates economic independence, engendering a sense of a purpose and accomplishment. However, for many adults on the autism spectrum the process of finding and securing a job remains challenging. A variety of environmental factors may influence the employment process, particularly employers, who play a central role in hindering or facilitating work participation for individuals on the autism spectrum. Yet, few studies exist exploring employers' capacity in hiring and supporting employees on the autism spectrum, and even fewer have considered interventions and strategies targeting employers' skills, abilities and knowledge in enhancing employment opportunities.
Objectives: To evaluate the effectiveness of an autism-specific workplace tool, the Integrated Employment Success Tool (IEST^{TM}), in improving employers' self-efficacy and knowledge in modifying the work environment to meet the specific needs of their employees on the autism spectrum.

Methods: A two-armed randomised controlled trial (RCT) was employed to evaluate the effectiveness of the IEST^{TM} intervention, by comparing employers (N=84) who used the IEST^{TM} with employers receiving employment support services as usual. Measurements were obtained at baseline and 12-weeks later at post-test. Measurements included self-efficacy in relation to implementing autism-specific workplace modifications using the Employment Self-Efficacy Scale and attitudes towards disability in the workplace using the Scale of Attitudes Toward Workers with Disabilities**.**

Results: Intention-to-treat analysis revealed a significant improvement in self-efficacy within the IEST^{TM} group between baseline and post-test (p=0.016), indicating participants increased their confidence in supporting employees on the autism spectrum by modifying the work environment. At post-test, there were no significant differences between groups in relation to self-efficacy in implementing autism-specific workplace modifications and employer attitudes towards disability in the workplace. Subgroup analyses were conducted to further explore whether then intervention dosage of the IEST^{TM} effected self-efficacy and attitudinal outcomes. Results were found to be similar to the intention-treat-analysis, with no significant differences between groups at baseline and post-test respectively.

Conclusions: The RCT found evidence that an autism-specific workplace tool for employers led to significant improvements in their confidence in modifying the work environment to meet the specific needs of their employees on the autism spectrum. These findings are consistent with the concept that implementing an intervention that increases knowledge, increases self-efficacy. While no significant attitudinal improvements were found, participants generally held favourable attitudes towards autism in the workplace, most likely influenced by previous experience, larger organisations and external support. Lastly, the IEST^{TM} was considered a useful tool for both new and existing employers in assisting them in modifying and managing the workplace, particularly during the interim of their regular assigned visits from disability employment service providers. The findings of the current study could be enhanced by further conducting a process evaluation to better interpret the outcomes of the interventions.

3:04 **189.003** A School-Based Transition Intervention for Adolescents with ASD: A Pilot Efficacy Study

K. M. Dudley[1]*, L. G. Klinger*[2]*, G. Osborne*[3]*, T. Dawkins*[4]*, R. K. Sandercock*[5] *and M. R. Klinger*[6]*, (1)Department of Psychology & Neuroscience, UNC Chapel Hill; TEACCH Autism Program, Carrboro, NC, (2)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC, (3)UNC TEACCH Autism Program, Greensboro, NC, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Department of Psychology & Neuroscience, University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)UNC TEACCH Autism Program, Chapel Hill, NC*

Background: Research indicates that persons with high functioning autism spectrum disorder (HFASD) have poor employment and post-secondary outcomes (Roux et al., 2013). Taylor et al. (2012) reported that only five evidence-based intervention papers addressed vocational skills in adults with ASD and all were of poor quality. For students enrolled in the general education high school curriculum, there has been little opportunity to support the soft skills difficulties (e.g., executive function, social competence, and emotion regulation) that are associated with poor college and employment outcomes.
Objectives: The current study used a waitlist control design to examine the efficacy of a 21-session, manualized high school-based transition intervention (TEACCH School Transition to Employment and Post-Secondary Education Program; T-STEP) addressing executive function (EF), social competence, and emotion regulation skills.

Methods: Participants were 37 high-schoolers (32 males; *M* age=16.79) with HFASD (FSIQ>85). Participants received 21 group intervention sessions (twice weekly for 90 minutes). Interventionists were a university-clinic therapist partnered with a special educator. At baseline, an abbreviated IQ test (WASI-II) and ASD diagnostic measures (ADOS-2, SRS-2) were completed. At baseline and post-testing (20 participants received the intervention; 17 were in the waitlist control group), caregivers completed a measure of real-world executive function (BRIEF) and a measure of employability skills including EF and interpersonal relations (Becker Work Adjustment Profile, BWAP). Additionally, teens participated in a semi-structured, 1-hour mock employment observation developed for this project (Job Skills Assessment Profile; JSAP) that incorporated presses for executive function, social, and emotion regulation skills targeted by the intervention. JSAP videos were coded by blind raters for 26 participants, and coding is ongoing for remaining participants.

Results: There were no significant differences between groups on IQ or ASD symptom variables (*p*'s=.26-.99). Three separate 2(time) X 2(condition) ANOVAs (BRIEF, BWAP, JSAP) were conducted to examine whether those in the intervention group showed more improvement compared to those in the waitlist control group. Significant time-by-condition interactions with medium-large effect sizes were obtained across all measures: BWAP, *F*(1,34)=3.98, *p*=.05; BRIEF Composite, *F*(1,34)=3.96, *p*=.06; and JSAP Composite, *F*(1,23)=4.18, *p*=.05. Largest effects were seen for the BWAP Work Performance (*p*=.02) and Interpersonal Relations (*p*=.05) subscales, for the BRIEF Metacognitive Index (*p*=.04), and the JSAP emotion regulation (*p*=.03) subscale. No effects were observed in areas that were not targeted by the intervention (e.g., the Cognitive Skills and Work Habits indices of the BWAP).

Conclusions: This pilot study provides promising evidence for the efficacy of the T-STEP as a transition intervention for high school students with ASD who are completing a general education high school curriculum. Improvements were found across both parent report and blind observation measures of the executive function, social competence, and emotion regulation skills targeted by this intervention. Results also support the feasibility of implementing the T-STEP in a school-based setting. Future research is needed to replicate these findings within a larger sample, to examine moderators of treatment effectiveness (e.g., symptom severity, intellectual functioning), and to follow students through graduation to examine long-term postsecondary and employment outcomes.

3:16 **189.004** Communityworks Canada® (CWC): A Volunteer, Pre-Employment Program for Youth with ASD

W. Mitchell[1], *C. Dudley*[1], *D. B. Nicholas*[2] *and R. Zulla*[3], *(1)Sinneave Family Foundation, Calgary, AB, Canada, (2)University of Calgary, Edmonton, AB, Canada, (3)University of Alberta, Edmonton, AB, Canada*

Background:

Evaluation of interventions that foster vocational skills in conjunction with social skills to prepare youth with Autism Spectrum Disorders (ASD) for employment are needed (Walsh, Lyndon & Healey, 2014). Community*Works* Canada® (CWC), a federally funded, peer supported program for youth aged 15-21 years aims to improve employment prospects through pre-employment training and exposure to volunteer work experiences. The 12-week program, delivered once per week for 2.5 hours is modeled after a volunteer training program developed by the Southwest Autism Research and Resource Center (SARRC) in Phoenix, USA.

Objectives:

Does the program influence the work readiness skills and social skills of participants?

Methods:

A convergent parallel mixed methods design (Creswell, 2014), involving in-depth interviews and quantitative data from questionnaires was used to complementarily examine outcomes and perceptions of participants involved in CWC. Qualitative data were transcribed verbatim and analyzed using NVivo 10 (QSR International, 2012) and questionnaire data identified pre/post differences. Questionnaires included:

1. The *Work Readiness Inventory (WRI*; Brady 2010), a 36-item self-report that identifies six areas crucial to work readiness: Responsibility, Flexibility, Skills, Communication, Self-view, and Health and Safety. Higher scores suggest increased concerns or areas of weakness.
2. The *Social Skills Improvement System (SSIS*; Gresham & Elliot, 2008), a parent-report questionnaire, measures behaviors that may interfere with an individual's ability to perform or acquire social skills using standardized scores (*M*=100, *SD*=15).

Fifty-one participants from six Canadian provinces were included in the preliminary data analysis (Table 1) and X participants, x participant's parents completed an interview.

Results:

Qualitatively, gains by participants were primarily noted in work preparedness and social skills, the primary foci of the program. Participants and parents indicated that the program enabled participants with ASD to explore employment particularly by learning about different types of jobs, learning about work preferences, and differentiating between work and leisure. Gaining work experience provided affirmation to individuals with ASD about their ability to complete job tasks and work with others, and increased self-confidence was a recurrent topic. Employment related gains were noted on the WRI (Table 2) that corroborated qualitative data. Social skills gained, as reported by participants with ASD and observed by parents, peer mentors and community partners, included: learning to interact (e.g. how to approach people), building communication skills (e.g. learning to listen quietly and take turns), fostering co-operation (e.g. learning to build motivation among others) and learning the value of social cues (e.g. understanding the importance of personal space). Results from the SSIS approached significance (p= .062; Table 2).

Conclusions:

Overall, findings demonstrate benefits from engaging youth with ASD in employment-oriented, inclusive efforts fostering individual skill building and employment exposure. Program outcomes include core skill acquisition and constructive experiential gain toward youth proficiency and comfort within work settings.

1:45 **190.001** Contextual Priors Do Not Modulate Action Anticipation in Children with Autism

L. Amoruso[1,2], ***A. Narzisi***[3], *M. Pinzino*[4], *A. Finisguerra*[5], *F. Fabbro*[5], *A. Volzone*[6], *S. Calderoni*[7], *F. Muratori*[4] *and C. Urgesi*[8,9], *(1)Univerisity of Udine, Udine, Italy, (2)Basque Center of Cognition, Brain and Language, San Sebastian, Spain, (3)IRCCS Fondazione Stella Maris, Calambrone (Pisa), Italy, (4)IRCCS Stella Maris Foundation, Calambrone (Pisa), Italy, (5)University of Udine, Udine, Italy, (6)Scientific Institute IRCCS Eugenio Medea, San Vito al Tagliamento, Italy, (7)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (8)Dipartimento di Lingue e Letterature, Comunicazione Formazione e Società, Uniersity of Udine, Udine, Italy, (9)Scientific Institute (IRCCS) E. Medea, Bosisio Parini, Italy*

Background: Current influential models on action comprehension postulate that optimal intention inference requires the combination of two sources of information:
(a) the observers' prior expectations about the likely intention driving other's behaviors, given past experiences; (b) the sensory evidence conveyed by online perceptual movement kinematics.

Objectives: Here, we aimed to investigate the ability of children with ASD to extract regularities from the environment and use them to build-up prior expectations about other's behavior.

Methods: 22 High-functioning ASD children were evaluated with the ADOS-2. Non-verbal IQ scores were derived, in ASD and Typycal control group (n=22), from the Raven's Colored Progressive Matrices. Paradigm: (1) Familiarization Phase (Fig.1): Implicit Probabilistic Learning Task. Children observed videos (1slong) depicting a child actor grasping common objects to perform different actions and we asked them to recognize actor's intention. Importantly, we implicitly biased action-contextual cues associations in terms of their probability of co-occurrence (i.e., given the presence of an orange plate, it was highly probable that the child would grasp the apple for eating); (2) Testing Phase: Action Prediction Task. Children observed the same videos but, in this case, the secondhalf remained occluded from view (500mslong) and participants were asked to predict action unfolding. During this phase, all possible action-contextual cues associations were equally presented. We reasoned that during this phase, where movement kinematics were partially occluded, children's responses would be biased to contextual priors acquired during the familiarization phase, thus compensating perceptual uncertainty.

Results: A) An independent t-test comparing the overall accuracy during the familiarization phase revealed no differences (t(46) = -1.34, p = 0.18) between ASD (M = 0.87, SEM = 0.03) and typically developing (TD, M = 0.93, SEM = 0.02) children in recognizing actor's motor intention. B) The RM-ANOVA revealed a significant Group by cooccurrence probability interaction [F(3, 138)=2.89, p=0.03]. Black solid lines indicate between-group comparisons, grey dotted lines within-group comparisons. Bars denote SEM.

Conclusions: No differences were observed between groups in recognizing actor's intention during the familiarization phase. However, when perceptual evidence was ambiguous, only TD children were able to combine it with contextual priors and successfully predict action unfolding in a probabilistic modulated fashion. Collectively, our results suggest that ASD children have an impairment in building contextual priors and do not benefit from them (i.e., integrate with perceptual evidence) when predicting other people's actions under situations of perceptual uncertainty.

1:57

190.002 Visual Motion Prediction and Verbal False Memory Performance in Autistic Children

*F. G. Tewolde, D. V. Bishop and **C. Manning**, Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom*

Background: Recent theoretical accounts propose that atypical predictive processing has a causal role in many aspects of the autism phenotype, from sensory processing to social symptoms (e.g., Sinha et al., 2014). Moreover, difficulties making predictions may be related to reduced contextual processing, as the ability to make good predictions requires using contextual information about the situation at hand, and generalising from similar situations experienced previously. Despite the potential of these new theoretical accounts, there is relatively little empirical evidence for disordered prediction in autism.

Objectives: In this study we tested three hypotheses. First, we hypothesised that autistic children would make less precise (i.e., more variable) predictions than typically developing children in visual extrapolation tasks, and that group differences would become more pronounced as children were required to make predictions over longer timescales. Second, we hypothesised that autistic children would be less susceptible to false memories, in line with reduced contextual processing. Third, we hypothesised that reduced precision in the prediction task would be related to increased sensitivity in the false memory task.

Methods: The study was pre-registered prior to data collection (https://osf.io/pv4w6/register/565fb3678c5e4a66b5582f67). Thirty autistic children aged 6-14 years and 30 typically developing children matched in age and non-verbal IQ completed visual extrapolation and verbal false memory tasks to assess predictive abilities and contextual processing, respectively. In the visual extrapolation tasks, children were asked to predict when an occluded car would reach the end of a road and when an occluded set of lights would fill up a grid. In the false memory task, children were asked to remember word lists and were then given a recognition test including semantically related, non-presented items. Where non-significant group differences were obtained, we used Bayesian analyses to quantify evidence for the null hypothesis.

Results: In the extrapolation tasks, autistic children made predictions that were just as precise as those made by typically developing children, across a range of occlusion durations. In the false memory task, the autistic and typically developing children did not differ significantly in their discrimination between items presented in a list and semantically related, non-presented items, although the data were insensitive, suggesting the need for larger samples. Insofar as there were relationships between performance in the two tasks, they were opposite to our hypothesis, with children who were more sensitive in the false memory task showing less variable performance in the extrapolation tasks. This relationship may reflect domain-general factors (e.g., motivation) or the involvement of a memory component.

Conclusions: Our findings provide an important test of rapidly developing theories and suggest that autism is not characterised by pervasive impairments in prediction. Prediction difficulties may well become apparent when making predictions between events that are more weakly associated, such as those involved in social interactions, or when it is important to decide what information is relevant to use for prediction. Further studies will be required to assess the relationship between predictive processing and context use in autism, and to establish the conditions under which predictive processing may be impaired.

2:09

190.003 Interoceptive Impairments Do Not Lie at the Heart of Autism or Alexithymia

***T. Nicholson**[1], D. M. Williams[2], C. Grainger[3], S. B. Gaigg[4], B. Calvo-Merino[4] and J. F. Christensen[5], (1)University of Kent, Canterbury, England, United Kingdom, (2)University of Kent, Canterbury, United Kingdom, (3)University of Stirling, Stirling, United Kingdom, (4)City, University of London, London, United Kingdom, (5)Psychology, City, University of London, London, United Kingdom*

Background: Background: Quattrocki and Friston (2012) argued that abnormalities in interoception–the process of bringing internal physiological states to awareness–could lie at the heart of autism, because of the critical role interoception plays in the ontogeny of social-affective processes. This proposal drew criticism from proponents of the alexithymia hypothesis, who argue that social-affective and underlying interoceptive impairments are not a feature of autism per se, but of alexithymia (a condition characterised by difficulties describing and identifying one's own emotions), which commonly co-occurs with autism. Despite the importance of this debate, direct empirical evidence is scarce and inconsistent.
Objectives: To test competing theories of autism (and self-awareness in this disorder).

Methods: Experiment 1 examined in a sample of 137 neurotypical individuals the association among autistic traits (measured using the Autism-spectrum Quotient; AQ), alexithymia (measured using the TAS-20), and interoceptive accuracy (using a standard heartbeat tracking measure). The heartbeat tracking measure required participants to close their eyes and, without taking their pulse, silently count their heartbeat during four different time intervals (25, 35, 45 and 100 sec). A pulse oximeter attached to participants' index finger measured actual heart rate. The closer the estimated heartbeats to the actual number of heartbeats during each interval, the better the interoceptive accuracy. In Experiment 2, interoceptive accuracy was assessed in 46 adults with ASD (27 of whom had clinically-significant alexithymia) and 48 neurotypical adults. Bayesian analyses were employed to complement null hypothesis significance testing ($BF_{10} < 1$ = evidence for the null; $BF_{10} > 3$ = evidence for the alternative hypothesis).

Results: Experiment 1 confirmed strong associations between autistic traits and alexithymia ($r = .42$, $p <.001$, $BF_{10} > 100$), but yielded no evidence to suggest that either was associated with interoceptive difficulties (rs < -.11, ps > .22, $BF_{10} < 0.22$). Those participants with scores above the cut-off alexithymia on the TAS-20 were assigned to a "high alexithymia" group ($n = 30$) and those with scores below the cut-off to a "low alexithymia" group ($n = 107$). There were no significant differences between these two groups in terms of levels or patterns of performance on the heartbeat tracking task, contrary to the alexithymia hypothesis (ps > .30, ds < 0.22, $BF_{10} < 0.35$). Reliability of all findings was confirmed by randomly splitting the total sample into two groups of $n = 68$ and 69 participants and re-analysing the data in each sub-sample. Results were identical in each subsample and always supported the null. Similarly, Experiment 2 provided no evidence for interoceptive impairments in autistic adults ($p = .53$, $d = 0.13$, $BF_{10} = 0.26$), and neither was interoceptive accuracy associated with either AQ (or ADOS) score or TAS-20 score in either diagnostic group.

Conclusions: The observations pose a significant challenge to notions that interoceptive impairments constitute a core feature of either ASD or alexithymia, at least as far as the direct perception of interoceptive signals is concerned. Instead, they support the theory that detection of physical states is undiminished in ASD.

2:21 **190.004** Domain-Specific Impairment in Flexible Value Learning in Young Children with ASD

Q. Wang[1]*, L. DiNicola*[2]*, P. Heymann*[1]*, M. Hampson*[3] *and K. Chawarska*[1]*, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Yale School of Medicine, Yale University, New Haven, CT*

Background: Limited selective attention toward social objects such as faces constitute one of the core symptoms of autism. Evidence from both human and primate studies suggests that the process of selecting objects for processing is guided by the appraisal of object values. Here we tested a hypothesis that impairments in selective attention in ASD may reflect a disruption of a system supporting learning about object values in social domain.

Objectives: To compare the value learning in social (faces) and nonsocial (fractals) domains on selective attention in young children with ASD and typically developing (TD) controls.

Methods: Participants included children with ASD (n=26, age M=44.0±17.3) and TD controls (n=28, age = 38.3±13.6). All children were tested with a novel gaze-contingent task employing instrumental reversal learning. The task design was inspired by a value learning task previously developed and validated in non-human primates (Kim et al., 2013). The task consisted of 4 blocks, each block consisted of training and testing trials (Subplot A). Training: The same two objects, either two fractals or two faces, were presented in all blocks. Within each block, one object was assigned an *a priori* high-value (HV) and the other one a low-value (LV). If a child looked at a HV object, the object became dynamic, turning into a smiling face (Social) or a colorful fractal animation (Nonsocial). Fixation on the LV object resulted in no changes. Test: The two HV and LV objects from the training trials were presented simultaneously. A saccade toward the HV object activated its dynamic display; a saccade toward the LV object resulted in no change of the display. The proportion of test trials during which a child fixated on the HV object #HV /(#HV + #LV) across all testing blocks served as a dependent variable (%HV).

Results: An ANOVA on %HV revealed no significant effect of diagnosis ($F(1, 43)=2.21$, $p = .144$), or condition ($F(1, 43)=.59$, $p=.542$ but a significant diagnosis x condition interaction ($F(1, 43)=8.88$, $p=.005$). Between-group comparisons showed no significant difference in the Nonsocial condition ($p=.577$, $d=.29$) but a significant TD group advantage in the Social condition ($p = .007$, $d = .85$).(Subplot B) Within-group contrasts showed that, following training, the bias toward HV objects in the TD group in the Social condition was stronger compared to the Nonsocial condition ($p=.007$), but this bias was comparable between conditions in the ASD group ($p=.164$). A significant correlation between performance in the Social and Nonsocial conditions was found in the ASD group ($r(22) =.47$, $p=.025$) but not in the TD group ($r(24) = .086$, $p=.689$).(Subplot C).

Conclusions: Children with ASD exhibit domain-specific impairments in value learning which may impact their attention in natural environments. Unlike their typically developing peers, children with ASD's learning in social and nonsocial domains may rely on the same underlying neural mechanism. These findings have implications for designing novel treatments targeting impaired selective attention to social targets and for studies of neural mechanisms of value learning in autism.

Cognition: Attention, Learning, Memory
191 - From Cognition to Symptoms

2:40 PM - 3:30 PM - Willem Burger Zaal

2:40 **191.001** Children with Autism Spectrum Disorder Prefer Looking at Repetitive Movements in a Preferential Looking Paradigm

Y. Hu[1]*, Q. Wang*[1]*, D. Shi*[1]*, Y. Zhang*[2]*, X. Zou*[3]*, S. Li*[1]*, F. Fang*[1] *and L. Yi*[4]*, (1)Peking University, Beijing, China, (2)Peking University, beijing, China, (3)The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China, (4)School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China*

Background: Individuals with ASD have been reported to show abnormal visual attention, including reduced attention at others' faces and eyes (e.g., Frazier et al., 2017; Tanaka & Sung, 2016), and abnormal visual preference for non-social objects (e.g., Chawarska et al., 2013; Sasson & Touchstone, 2014). Unlike the abnormal attention related to social stimuli, the visual abnormality related to the restricted interests and the repetitive behaviors has attracted limited research attention. The assessment of repetitive behavior in ASDs was mostly based on subjective reports from parents or clinical observations (e.g., Autism Diagnostic Observation Schedule; Lord et al., 2000). Several studies have examined the repetitive behaviors related stimuli (RBRS) in ASD by displaying RBRS and social stimuli simultaneously (Pierce et al., 2011; Pierce et al., 2016; Sasson & Touchstone, 2014). Considering the limitation of the interference of social stimuli in previous studies, the present study aimed to examined the visual preference for the repetitive movements in young children with ASD.

Objectives: The present study was designed to examine the visual preference for the repetitive movements in young children with ASD.

Methods: Twenty young children with ASD (2.74 - 5.24 years old) and 20 IQ- and age-matched typically-developing (TD) children were presented simultaneously with repetitive movements (e.g., a butterfly flying in a circle route) and random movements (e.g., the same butterfly flying in a random route). A Tobii Pro X3-120 eye tracker recorded children's eye movements simultaneously. Two areas of interest (AOIs) were defined for the two different moving patterns in each trial: the repetitive movement AOI and the random movement AOI. We analyzed total looking time on the repetitive and the random movements for each trial, and computed the average proportional looking time on the repetitive AOI against the total looking time on both the repetitive and the random AOIs, defined as dynamic repetitive preference index (RPI). we also conducted a temporal course analysis of the RPI by dividing each trial into three phases (early, middle, and late phases, each phase lasting for approximately 31 seconds). A well above chance level (50%) RPI represents a looking preference for the repetitive movements over the random movements. Parent

reports were accessed using Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al., 2000).

Results: As shown in Figure 1 and Figure 2, We found that: (1) children with ASD spent significantly more time fixating on the repetitive movements than the random movements, whereas TD children showed no preference for either type of movements; (2) temporal course analysis further revealed that, this preference for the repetitive movements in ASD emerged as early as the first 30 seconds; (3) children's preference for repetitive movements was correlated with the severity of repetitive behaviors based on parent reports, but not with their ages and cognitive functions.

Conclusions: Our findings not only reveal the gaze abnormality of ASD beyond the previously reported atypical social attention, but also show a promise in using the preferential looking as a potential indicator for the repetitive behaviors and aiding early screening of ASD in future investigations.

2:52 **191.002** Reconciling the Co-Occurrence of Impulsivity and Insistence on Sameness in ASD

D. J. Bos[1], *M. R. Silverman*[1], *E. Ajodan*[1], *C. Martin*[2], *B. Silver*[3], *A. Di Martino*[4] *and R. M. Jones*[3], *(1)Sackler Institute for Developmental Psychobiology, New York, NY, (2)Weill Cornell Medicine, White Plains, NY, (3)Weill Cornell Medicine, New York, NY, (4)The Child Mind Institute, New York, NY*

Background: Children with autism spectrum disorder (ASD) often have intense or odd interests that can negatively impact adaptive behavior and social interactions. It is unknown whether such interests can bias self-control in children with ASD.

Objectives: The aim of this study was to investigate impulse control towards interests in ASD. We expected children with ASD would show a greater sensitivity, reflected by increased impulsivity, towards stimuli depicting their interests versus their non-interests.

Methods: 100 children aged 6-12 yrs who were either typically developing (TD) or had ASD performed a novel go/nogo task to cues of their interest versus cues of non-interest on an iPad. Children chose their favorite (interest) and least favorite hobby/activity (non-interest) from 23 options. One category of cues served as the go-stimulus (e.g. interests) to which participants were instructed to touch the image on the iPad-screen as fast as possible and the other category of cues served as the nogo-stimulus (e.g. non-interests) for which participants withheld their response. Go and nogo stimuli were counterbalanced across two runs. False-alarm rate was calculated as the number of erroneous button presses to the nogo cue in each run. D-prime (*d'*) was calculated as the normalized hit rate (go-accuracy) – normalized false alarm rate. Using Linear Mixed-Effects models differences in hit rate, false alarms and *d'* were tested with task condition, diagnostic status and age as fixed factors, and within subject variability as a random factor. Caregivers also completed the Repetitive Behavior Scale - Revised (RBS-R) to provide a measure of the severity of repetitive behaviors and the Strengths and Weaknesses of ADHD symptoms and Normal behavior (SWAN) to measure the children's inattention and hyperactivity/impulsivity.

Results: Children with ASD were more impulsive towards their interests as shown by an interaction effect between task condition and diagnostic status on *d'* ($F_{(1,73)}$ = 5.4, p = .024). This interaction was driven by a lower *d'* to interests as compared to non-interests in children with ASD (ß = -0.29, s.e. = 0.11, p = .012, 95% CI = -.52 - -.07), in combination with lower *d'* to interests in children with ASD compared to TD children (ß = -0.39, s.e. = 0.18, p = .029, 95% CI = -.74 - -.04)(Figure 1). Interestingly, impulsivity towards interests (*d'*) was specifically associated with higher caregiver reports of insistence on sameness behaviors on the RBS-R in children with ASD (r = -.39 , p = .016; Figure 2). Furthermore, across TD children and children with ASD, symptoms of ADHD measured by the SWAN specifically correlated with *d'* to interests (r = -.46 , p < .001). There were no correlations with d' to non-interests.

Conclusions: These findings suggest some children with ASD may present with both insistence on sameness behaviors and difficulties with impulsivity, two behaviors that could be perceived as mutually exclusive. As interests negatively influenced self-control in children with ASD, using a child's personalized interest as a reinforcer during clinical intervention may be challenging.

3:04 **191.003** Cross-Domain Cognitive Subgroups of Autism Spectrum Disorder Show Differences Both in Terms of Their Clinical Symptom Profile and Neurofunctional Characteristics: Evidence from the EU-AIMS LEAP Cohort

Background: The immense clinical and etiological diversity among people with Autism Spectrum Disorder (ASD) is now well established. This has shifted the research focus from identifying *diagnostic* markers to the discovery of *stratification* markers to parse the umbrella condition into more homogeneous subgroups. For example, at the cognitive level, no single marker has been found that characterizes all individuals with ASD. We recently highlighted this by contrasting case-control comparisons with normative modeling approaches on a set of cognitive tasks tapping theory of mind (ToM), executive function (EF), and weak central coherence (WCC). Akin to growth curves, normative modeling allows one to define each individual in terms of their deviation from age-expected means. Despite significant mean-group differences on each of these tasks, the

majority of people with ASD in fact performed within 1 Standard Deviation of their age-expected TD group means (Fig 1 a,b). Next, we used hierarchical clustering to identify cognitive subgroups based on individual performance profiles across cognitive domains. This yielded three clusters, which can be characterized as Subgroup 1: EF impairments, Subgroup 2: intact cognition across-the-board, and Subgroup 3: impaired ToM+EF (Fig 1c). We then demonstrated significant differences in the clinical symptom profile between the three groups, such that Subgroup 3 had significantly more severe ASD core symptoms than the two other groups (Fig 1d) while Subgroup 2 had significantly fewer associated ADHD symptoms and higher levels of adaptive behavior than the two other groups. (Fig 1f). However, one important question remained: do these subgroups also differ in their neurobiological underpinnings?
Objectives: To investigate neurofunctional differences between cognitive subgroups on 1) an fMRI ToM “Animated Shapes Task”, and 2) an fMRI executive function “Flanker/NoGo Task”.

Methods: The present analyses focused only on individuals with a clinical diagnosis of ASD. Participants were assessed as part of the multi-site EU-AIMS LEAP cohort and included in this project if data on the cognitive subgrouping analyses as well as fMRI data on the ToM task (N=139) and/or Flanker task (N=123) were available. fMRI data from all study centres were preprocessed in a common pipeline using SPM12. To investigate differences in functional activation between the three subgroups we used both region-of-interest approaches (comprising areas involved in the ToM and EF networks, respectively) and exploratory whole-brain voxel-wise analyses. Site was included as covariate throughout.

Results: On the Animated Shapes task (contrast “ToM> random”) we found a significant activation difference between subgroups 3 and 1 (whole brain p<corr>=.01; ROI p_{corr}=.01) in the right middle temporal gyrus; a region previously implicated in ToM processing (Fig 1e). On the Flanker Task (contrast “[NoGo+incongruent] >[neutral+congruent]”) whole-brain analyses showed a significant effect of cluster (p_{FWE}=.017) on right superior frontal gyrus- with subgroup 2 showing significant deactivation compared to subgroup 1 (Fig 1g).

Conclusions: We herein report first evidence for cognitive subgroups that differ on average in both clinical symptom profile and neurofunctional characteristics. To validate these cross-domain cognitive subgroups as stratification marker for ASD, replication of findings will be essential.

3:16 **191.004** Flexibility Explains Adaptive Behavior in Youth with Autism Spectrum Disorder

J. R. Bertollo[1], *J. F. Strang*[2], *S. Seese*[3], *L. Kenworthy*[3], *G. L. Wallace*[4,5] *and B. E. Yerys*[1], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Center for Autism Spectrum Disorders, Children's National Health System, Washington, DC, (3)Children's National Health System, Washington, DC, (4)National Institutes of Health- National Institute of Mental Health, Bethesda, MD, (5)The George Washington University, Washington, DC*

Background: Adaptive behavior, the ability to function independently in everyday life, is an important measure of functional outcomes for individuals with autism spectrum disorder (ASD). Individuals with ASD tend to achieve poorer outcomes and exhibit worse adaptive behavior than groups with other developmental disorders, to a degree that cannot be explained by IQ alone. Prior research points to the importance of flexibility, an executive function skill, as an important factor predicting adaptive behavior in school-age youth with ASD. However, this research was limited to an 8-item informant-report measure of flexibility that was not designed to measure specific flexibility skills (e.g., flexibility in thought, routines, or social behavior). With our team’s recent publication of the Flexibility Scale, we now have a multi-dimensional parent-report measure. Identifying which flexibility skills relate to adaptive behavior will help us better tailor treatments to increase an individual’s ability to function independently in daily activities.
Objectives: To examine specific flexibility skills that relate to an individual’s level of adaptive behavior.

Methods: Participants included 216 individuals with ASD (mean age=10.67 years, 83.3% male). Adaptive behavior was measured by the Vineland Adaptive Behavior Scales, First and Second Editions. Flexibility was assessed by the Flexibility Scale-Revised, which includes 27 items pertaining to Social Flexibility, Routines and Rituals, Transitions/Change, Special Interests, and Generativity. Flexibility skills, captured on the 8-item Shift scale from the Behavior Rating Inventory of Executive Function (BRIEF), were also examined, to check for replicability from prior research that utilized this measure. To evaluate the role of flexibility above and beyond covariates of age, IQ, and gender, three stepwise regressions were conducted, one for each Vineland domain. The first step evaluated covariates; the second step added the five Flexibility Scale-Revised Subscales. We hypothesized replicating prior findings of BRIEF-Shift scale scores associating with Vineland Socialization skills, while further specifying this association as driven by Social Flexibility deficits, using the more granular Flexibility Scale-Revised.

Results: In line with prior literature, the BRIEF-Shift scale was significantly associated with Vineland Socialization skills ($p<0.001$). When examining the multi-dimensional Flexibility Scale-Revised, as hypothesized, Social Flexibility accounted for significant variance in Socialization skills, as did Generativity and Routines and Rituals. Together, the Flexibility Scale-Revised subscales contributed 26.8% of variance in Socialization skills ($p<0.001$). Additionally, Flexibility Scale-Revised subscales explained 9.3% of variance in Daily Living Skills ($p<0.001$), with Generativity reaching statistical significance. Flexibility Scale-Revised subscales, particularly Generativity, Routines and Rituals, and Transitions/Change, explained 15.9% of variance in Communication skills ($p<0.001$).

Conclusions: As predicted, a more granular measure of flexibility impairments replicated and specified prior relationships with social adaptive functioning skills. It also showed strong relationships with other areas of adaptive behavior that were not seen with the BRIEF-Shift scale alone. Future studies should examine both the predictive value of specific flexibility skills with longitudinal outcomes, and convergence with performance-based measures at a single time point. Furthermore, dismantling the construct of flexibility into its subcomponents is critical for supporting a personalized treatment approach, so that children with flexibility deficits can receive more targeted supports to improve outcomes.

Health, Baltimore, MD, (2)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA, (4)University of North Carolina - Chapel Hill, Chapel Hill, NC, (5)Johns Hopkins School of Public Health, Baltimore, MD, (6)University of Colorado Denver School of Medicine, Aurora, CO, (7)Public Health, Aarhus University, Aarhus, Denmark, (8)Economics and Business, National Center for Registry-based Research, Aarhus University, Aarhus, Denmark, (9)Aarhus University, Aarhus, Denmark, (10)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (11)Centers for Disease Control and Prevention, Atlanta, GA, (12)Division of Research, Kaiser Permanente, Oakland, CA, (13)AJ Drexel Autism Institute, Philadelphia, PA, (14)A.J. Drexel Autism Institute, Philadelphia, PA

Background: Despite high heritability estimates for autism spectrum disorder (ASD), several recent studies show environmental factors, especially exposures during the prenatal window, play a larger role in ASD risk than previously thought. Genome-wide studies integrating genetic and environmental factors could provide further understanding of the contribution of environmental and genetic factors to ASD risk. Both technical and practical limitations have hindered this type of integrated study in the past. However, recent advances in gene-environment interaction (GxE) methods, as well as availability of environmental exposure, genetic, and phenotypic information on a large representative population of children, now make a genome-wide GxE study (GEWIS) for ASD feasible.

Objectives: Our primary study objective was to identify single nucleotide polymorphisms (SNPs) whose effects on ASD risk vary across levels of selected prenatal environmental exposures, including maternal alcohol, tobacco, and medication use, and maternal infections.

Methods: The Study to Explore Early Development (SEED) is a US multisite epidemiologic study of ASD with comprehensive phenotyping, broad prenatal environmental exposure information, and biospecimens available for DNA measurements. A total of 1,321 children, aged 2-5, enrolled in SEED phase 1 with a classification of ASD or population control (POP) were genotyped on the Illumina Omni1M or Affymetrix Axiom genome-wide genotyping platforms. After applying our rigorous quality control and imputation pipelines, using SHAPEIT, IMPUTE2, and the 1000 genomes reference panel (version3), we had a final analytic dataset of 1,307 samples (582 ASD and 725 POP) and over 16 million SNPs available for GxE analyses. Prenatal environmental exposure data were derived from retrospective maternal self-report using a structured interview. Specific exposures included maternal use of tobacco, alcohol, β-2 adrenergic receptor agonist or antidepressant medications, and any of 36 specific maternal infections. GxE analyses used two approaches: (1) a case-control likelihood ratio test (LRT) that allows for genetic main effects to be modified by exposures, and (2) a case-only LRT that overcomes problems with gene-environment dependence assumptions by utilizing an empirical Bayes-type shrinkage estimator. These two approaches were specifically designed to handle millions of genomic loci making this GEWIS effort on a moderately sized sample plausible.

Results: Using the case-only LRT, we identified a genome-wide significant interaction ($P<1\text{x}10^{-07}$) for prenatal exposure to alcohol and a locus on chromosome 15 within the *TRPM1* gene. This locus also reached a suggestive association threshold level using the case-control LRT method. The interaction effect estimate for both tests suggest a synergist interaction between the genetic variant and prenatal exposure. Several loci on chromosome 6 also reached suggestive significance ($P<1\text{x}10^{-05}$) for increased ASD risk among individuals with prenatal exposure to maternal infections. These were not located near the major histocompatibility genes but instead are located near a long non-coding RNA shown to have brain-region specific expression in the Genotype-Tissue Expression project.

Conclusions: We identified a genomic locus on chromosome 15 whose effect on ASD risk varies by levels of alcohol exposure during pregnancy, as well as an intergenic region on chromosome 6 showing suggestive association with ASD risk in the context of prenatal exposure to infection.

1:57 **192.002** DNA Methylation and Cross-Tissue Integration Shows Utility Of Blood-Based Epigenetic Research for ASD

Ladd-Acosta*[1], *(1)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Johns Hopkins School of Public Health, Baltimore, MD, (4)University of Michigan, Ann Arbor, MI, (5)Aarhus University, Aarhus, Denmark, (6)Centers for Disease Control and Prevention, Atlanta, GA, (7)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (8)Division of Research, Kaiser Permanente, Oakland, CA, (9)University of California at Davis, Davis, CA, (10)Human Genetics, Emory University, Atlanta, GA, (11)Psychiatry, University of Wisconsin, Madison, WI, (12)Johns Hopkins University, Baltimore, MD, (13)University of Exeter Medical School, University of Exeter, Exeter, United Kingdom, (14)Exeter Medical School, University of Exeter, Exeter, United Kingdom, (15)AJ Drexel Autism Institute, Philadelphia, PA, (16)Johns Hopkins University School of Medicine, Baltimore, MD*

Background: Epigenetic mechanisms have been implicated in ASD, including evidence from rare-variant genetics findings. Further, common variant GWAS studies for ASD have recently increased in size and precision. Few have integrated genetic and epigenetic findings in the same study of ASD, partly due to skepticism about the utility of blood-based DNA methylation studies for this brain-based disorder.

Objectives: This work aimed to take genome-wide approaches at the DNA methylation (epigenome-wide, EWAS) and SNP variant (GWAS) levels and to integrate information from both to elucidate biological insights not possible via either type of information in isolation.

Methods: DNA methylation was measured on 968 child blood samples from the Study to Explore Early Development (SEED 1) and 343 child-sibling pairs from the Simons Simplex Collection (SSC) using the Illumina 450K Beadchip array. We performed EWAS meta-analysis, after extensive data cleaning and adjustment, and compared top EWAS results to those from brain-based results. We also used a combination of GWAS SNP data and 450K array DNAm data measured on infant cord blood from the EARLI study and SEED child blood to identify SNPs associated with DNA methylation (meQTL lists) in these tissues. We tested for enrichment of methylation-QTL (meQTL) CpG targets in our EWAS results. We also took the reverse approach of exploring the most recent PGC-AUT GWAS results for enrichment of meQTLs across cord, peripheral blood and publicly available fetal brain and lung meQTL lists. We further assessed biological pathways implicated by ASD-specific meQTLS and their CpG targets.

Results: While no single CpG met epigenome-wide statistical significance ($p < 1.12\text{x}10^{-7}$) in our EWAS meta-analysis, 7 showed differences at $p < 1\text{x}10^{-5}$ and 48 at $1\text{x}10^{-4}$. Of the top 7, 5 showed brain-based ASD associations, often with larger effect sizes. We also observed suggestive evidence for enrichment of CpG sites controlled by SNPs (meQTL targets) among the EWAS hits. When considering GWAS hits, we previously discovered enrichment of ASD-associated SNPs for fetal brain (OR = 3.55; $P < 0.001$) and peripheral blood meQTLs (OR = 1.58; $P < 0.001$). The CpG targets of ASD meQTLs across cord blood, peripheral blood, and brain tissues showed enrichment for immune-related pathways, consistent with other expression and DNAm results in ASD, and revealed pathways not implicated by genetic findings alone. We will update these enrichment findings with the latest PGC-AUT GWAS hits for INSAR presentation.

Conclusions: We report the largest case-control EWAS study of ASD to date. Our results suggest the potential to observe disease associations from blood-based samples, given the concordance of findings between blood and brain EWAS among suggestive hits. However, the greater current utility may be in using DNAm data to inform GWAS results, where we observed enrichment of ASD-associated SNPs for meQTLs and showed involvement of immune biology when considering the epigenetic targets of these ASD SNPs. Our joint analysis of genotype and DNAm demonstrates the potential of both brain and blood-based DNAm for insights into ASD.

192.003 Genome-Wide Analyses of DNA Methylation in Autism Brains Suggest Epigenetic-Mediated Effects in GABA Signaling

__J. I. Young__[1], A. J. Griswold[2], C. Brandenburg[3], J. P. Hussman[4], M. A. Pericak-Vance[2], G. J. Blatt[3] and J. M. Vance[5], (1)John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, (2)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, (3)Hussman Institute for Autism, Baltimore, MD, (4)Hussman Institute for Autism, Catonsville, MD, (5)Hussman Institute for Human Genomics, Miami, FL

Background: Ample evidence supports involvement of the striatum and cerebellum in autism pathophysiology. Emerging evidence implicates altered DNA methylation as a likely contributing factor to autism etiology.
Objectives: In order to gain understanding of the role of DNA methylation and transcriptional regulation in autism, we profiled the methylome and transcriptome of striatal and cerebellar tissue from autistic and neurotypical individuals.

Methods: DNA and RNA were extracted from frozen striatum and cerebellar tissue from 5 autism cases and 5 neurotypical individuals obtained from the Maryland Brain and Tissue Bank. Samples were matched for age, sex and post-mortem interval. Methylation profiles were analyzed using MethylationEPIC bead arrays. As CpG methylation is often correlated amongst neighboring sites, we used differentially methylated regions (DMR) for this analysis. Differential gene expression was assayed through RNA-seq analysis. Differentially methylated genes (containing DMRs) as well as genes differentially expressed were further analyzed to determine functional pathways and ontology enrichment using the Enrichr web tool. In addition, transcription factor binding site enrichment was identified using oPOSSUM and GATHER-based analysis of TRANSFAC motifs.

Results: We found significant DMRs between cases and controls, including DMRs in genes previously implicated in autism. Pathway analysis of genes containing DMRs in the striatum indicates significant enrichment in the Kegg pathway “GABAergic synapse”, whereas the Kegg pathway “endocytosis” is enriched in the cerebellum. Both pathways have been previously postulated to contribute to autism pathophysiology.

RNA-seq based analysis of differential gene expression identified differentially expressed genes (DEG) with FDR <0.05 in both brain regions, including several that have been implicated in autism. Interestingly, pathway analysis found that striatal DEG genes were enriched for the Kegg pathway “Neuroactive ligand-receptor interaction” and the gene ontology category “GABA-A receptor activity”. Analysis of TFBS revealed enrichment of *PAX6* binding to striatal DEG genes. Our data also shows that *PAX6* contains a significantly hypomethylated DMR in striatum in autism individuals as well.

Conclusions: We have identified tissue-specific epigenomic alterations in autism brains, including alterations in known autism-associated genes. The etiology of these changes are not known, but could be inherited or due to environmental exposures during development. Both DMR and differential gene expression point to GABA signaling mechanisms as important in autism pathophysiology. These pilot data suggest that epigenetic evaluation of selected brain regions has high potential for autism studies. In addition, converging molecular alterations may provide insight into mechanisms of disease even with smaller sample sets than those required for genetic studies.

192.004 Characterization of SCN2A Haploinsufficiency in Early Neurodevelopment Using Transcriptomic Analyses and Systems Biology

J. Y. An[1], S. Fazel Darbandi[1], D. M. Werling[2], G. B. Schwartz[1], C. M. Keeshen[3], K. J. Bender[4] and __S. Sanders__[1], (1)Psychiatry, University of California San Francisco, San Francisco, CA, (2)Psychiatry, UCSF, San Francisco, CA, (3)UCSF, San Francisco, CA, (4)Department of Neurology, UCSF, San Francicso, CA

Background: *SCN2A* is a voltage-gated sodium channel gene that encodes neuronal sodium channel $Na_V1.2$ and plays a critical role in early neurodevelopment and action potential initiation. Large-scale genomic studies have demonstrated that *SCN2A* is associated with autism spectrum disorder (ASD), developmental delay, and seizures. Integrative analysis using electrophysiology and cellular data showed that ASD mutations impaired neuronal excitability in the developing brain ($Na_V1.2$ loss-of-function).
Objectives: To understand the functional consequence of SCN2A loss-of-function mutation during the neurodevelopment, and whether transcriptional changes in SCN2A haploinsufficiency converge on biological pathways related to ASD neurobiology, suggesting that biological findings may be relevant to ASD in general.

Methods: From a heterozygous SCN2A deletion mouse model (*Scn2a1*$^{wt/-}$), we collected samples from two developmental stages (postnatal day 7 (P7) and P30), equivalent to infancy and early adulthood in humans, and two brain regions (cortex and cerebellum). RNA-seq was performed on two biological replicates of these samples using a 50bp paired-end library. After adjusting for covariates, we identified differentially expressed genes in SCN2A deletion compared with wild-type littermates (SCN2A-DEX, ±1.5-fold change in expression; p-values ≤0.05 after Benjamini-Hochberg correction).

Results: We found distinct spatiotemporal gene expression changes in *Scn2a1*$^{wt/-}$ mice, largely for genes related to neuronal functions. Specifically, we found that SCN2A-DEX genes in the developing (P7) cortex are enriched for co-expression modules of synaptic genes in the ASD human postmortem cortex (Parikshak et al. 2016), as well as FMRP binding targets (Darnell et al. 2011). In addition, gene set enrichment analysis using cell type-specific expression profiles (Xu et al. 2014) showed that SCN2A-DEX genes are enriched in cortical projection neurons, particularly in layer 5 and 6 pyramidal neurons. This is consistent with our previous observation that SCN2A variants associated with ASD impair neuronal excitability in the developing pyramidal cell model (Willsey et al. 2013).

Conclusions: Our analysis of RNA-Seq data in this mouse model shows that *SCN2A* disruption in the developing cortex impacts numerous genes that have been highlighted in ASD pathology, suggesting that *SCN2A* and other causes of ASD may converge on common pathological pathways. Further characterization of *SCN2A* function may therefore provide an important window into the neurobiology of ASD.

Oral Session - 13B
Service Delivery/Systems of Care
193 - Service Access and Patterns of Care Across Service Systems
2:40 PM - 3:30 PM - Willem Burger Hal

2:40 **193.001** Using Diffusion of Innovation Theory to Improve Adoption of Evidence Based Practice in Community Settings: A 10-Year Case Study in PRT

***M. Stolte**, Centre for Autism Services Alberta, Edmonton, AB, Canada*

Background: Barriers to adoption of evidence-based practice in autism spectrum disorder treatment are numerous and there is a need for research on how better to bridge this gap between science and practice. Diffusion of innovation theory (Rogers, 2003) has been used to understand the adoption and rejection of new practices in a wide range of disciplines, such as agriculture and computing science, though has only rarely been applied to understanding autism treatment (Dingfelder & Mandell, 2011). This case study frames the adoption process of an evidence-based practice (EBP) over a 10-year period - Pivotal Response Treatment [PRT] (Koegel et al., 2006) - currently under dissemination in Western Canada by a large, non-profit autism service provider. This study extends previous research on evaluating EBP in community settings.
Objectives:

1. To summarize five key characteristics of diffusion of innovation theory: relative advantage, compatibility, complexity, trialability, and observability.
2. To apply these key characteristics to the adoption of PRT in a community-based setting, identifying successes and barriers in the adoption process.
3. To share these observations with other treatment providers and researchers to improve the adoption of EBP in community-based settings.

Methods: Using a case study framework, the 10-year adoption process of PRT was summarized, highlighting specific training models and methods of implementation of a large service provider in Western Canada. Diffusion of innovation theory was used to frame key aspects of the adoption process, highlighting successes and areas of difficulty. The primary focus was on the persuasion component of diffusion of innovation theory. Persuasion is associated with increased likelihood of adoption of an EBP, and by identifying key aspects, it is hypothesized this will allow other treatment providers to better understand how to use implementation science as a means of improving EBP adoption.

Results: A timeline of events was provided, including successes and setbacks in PRT adoption, in this practice setting. A clear description of the different implementation models trialed by the service provider were described, as well as training programs, quality control mechanisms, and areas of conflict and success. For each component of the persuasive element of diffusion of innovation theory, contrasting successes and sources of disagreement were identified. Themes emerged identifying agreement as well as challenges with the adoption process by program staff. Even 10 years after the adoption of this technology at a management level, full adoption of PRT at a practice level staff was still only partial, highlighting the challenges in disseminating EBP in existing practice environments.

Conclusions: Bridging the research to practice gap is difficult. This case study summarizes the experience of a large service provider in Western Canada with the adoption process of an EBP in this practice setting. Using diffusion of innovation theory, the adoption process is better understood, highlighting areas of success, as well as past and future challenges. This study demonstrates how difficult the implementation of EBP may be in community-based practice settings, and provides a framework for better understanding how to improve the implementation process of science-based practices in these settings.

2:52 **193.002** High Impact Vocational Services to Achieve Employment More Rapidly

***D. Nord**[1] and K. Hamre[2], (1)Indiana Institute on Disability and Community, Indiana University, Bloomington, IN, (2)School of Social Work, Indiana University, Bloomington, IN*

Background: Employment plays a critical role in social, emotional, and financial well-being for people with autism. With the various challenges associated with autism, many people face significant barriers to obtaining and maintaining a competitive job in the community. In the United States, this results in people with autism experiencing considerably lower employment outcomes. Central to improving employment for this population, it is critical to understand what services and key individual variables relate to quality outcomes.
Objectives: To identify high impact vocational services that increase the odds of employment for people with autism. To describe how education and age interact on the length of time to obtain a job. To test the moderating effect of high impact vocational services on the effect of education on the length of time to obtain employment.

Methods: This study analyzed a national vocational dataset from the U.S. Department of Education, Rehabilitation Services Administration. Subjects included all service users with autism as a primary or secondary impairment, who were unemployed at program entry. The resulting sample included 5,182 subjects. Analyses included logistic regression to model the odds of employment of all subjects and linear regression to model the months to achieve employment for the subsample that obtain a job prior to program exit (n = 2,695). Key variables were controlled in analyses, including significance of disability and educational policies affecting age cohorts.

Results: The study found people with autism entering the Vocational Rehabilitation Services program experienced 10 to 22 times higher odds ($p < .001$; pseudo $R^2 = .34$) of obtaining employment, compared to the reference group, if they received a combination of two or all three following three high impact supports; job search assistance, job placement assistance, and on-the-job supports. Additionally, subjects averaged 25 months to obtain employment. Education and age had a significant interaction effect ($p < .001$; $R^2 = .196$) on the number of months to obtain a job. The effects of education on reducing time to job acquisition are considerably stronger for older people with autism than younger. Finally, holding all else constant, high impact supports significantly moderated education's effect on the months to obtain employment ($p < .01$; $R^2 = .24$) by achieving the outcome four to 17 months sooner than those with the same education that did not receive the support.

Conclusions: Searching and obtaining a job is a difficult process, thus it is critical to target interventions and effort in ways that can produce effective and efficient results. This study highlighted the important relationships between specific high impact employment services and job attainment, a finding with direct policy and practice implications. Additionally, this study focuses needed attention on the relationship of education, age, high impact services, to investigate key variables that can reduce the time to obtain employment. These results have implications that can guide future causal research, as well as inform systemic policy and practices.

3:04 **193.003** The Influence of Individual and Family Characteristics on Intervention Access for People on the Autism Spectrum: A RI-CART Study

C. E. McCormick[1,2] *and S. J. Sheinkopf*[3,4,5,6]*, (1)Human Development and Family Studies, Purdue University, West Lafayette, IN, (2)Rhode Island Consortium for Autism Research and Treatment (RI-CART), Bradley Hospital, East Providence, RI, (3)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI, (4)Pediatrics, The Warren Alpert Medical School of Brown University, Providence, RI, (5)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, (6)Rhode Island Consortium for Autism Research and Treatment (RI-CART), East Providence, RI*

Background: If services were based solely on need, family characteristics would not influence intervention utilization; however, serval characteristics besides symptoms or functioning have been identified as influencing access to services (Bishop-Fitpatrick & Kind, 2017). Few studies have combined several child and family characteristics within the same model to examine which characteristics have the most influence on service utilization for people with Autism Spectrum Disorder (ASD).

Objectives: The goal of this study was to simultaneously examine factors related to service utilization in a large heterogeneous sample community based sample of participants with ASD.

Methods: Participants consisted of 521 individuals (N female = 106) from the Rhode Island Consortium for Autism Research and Treatment (RI-CART) who completed questionnaire information on service usage. Participants ranged in age from 2-20 years (M = 10.30, SD = 4.35). All participants received an Autism Spectrum Disorder (ASD) diagnosis in the community and met criteria for ASD on the ADOS-2. Parents or guardians indicated whether the following services had ever been used: Applied Behavior Analysis (ABA), Individual Family Services Plan/Early Intervention Plan, Individual Education Plan, occupational therapy, speech and language therapy, physical therapy, summer services, other (examples of services described when other selected included social skills and music therapy).

Poisson and logistic regressions were used to examine number of services endorsed and specifically whether ABA had been received. The following independent variables were included in the models: ADOS comparison score, sex, age, Vineland Adaptive Behavior Composite (VABS), age at ASD diagnosis, whether the mother had a partner (i.e. married or living with partner), participant identified as Hispanic, African American, or Asian, English as the primary language in the household, and maternal education (High school or less, some college or BA/BS, advanced degree).

Results: Identifying as Hispanic was associated with reduced likelihood of ABA utilization (OR=0.49, 95% CI 0.99, 0.24) and was associated to a marginal degree with reduced total services utilization (OR = 0.88, 95% CI 1.01, 0.77). Age of diagnosis was negatively associated with both total services (OR = 0.97, 95% CI 0.98, 0.95) and utilization of ABA (OR = 0.84, 95% CI 0.91, 0.77). Full model results are reported in Table 1.

Conclusions: The only family characteristic significantly associated with service utilization was identifying as Hispanic. The more significant barriers faced by this group stand out even when accounting for difficulties specific to families where English is not the primary language spoken in the home. When controlling for ASD symptoms and functioning, the participant's age of diagnosis was also a predictor of service utilization. Participants who received their diagnoses at older ages were less likely to receive services in both the model predicting total services and when predicting ABA service utilization. These findings highlight the importance of early identification by demonstrating how health disparities at one level of service delivery can have cascading effects.

3:16 **193.004** Care Coordination:Testing Associations between Social Networks and the Perceived Transition Success for Low Resource Children with ASD

E. McGhee Hassrick[1]*, W. I. Shih*[2]*, C. Friedman*[1]*, Z. Shamsi*[3]*, S. F. Vejnoska*[4]*, B. Bronstein*[5]*, D. E. Linares*[6]*, K. M. Carley*[7]*, A. C. Stahmer*[8]*, T. Smith*[9]*, P. Mundy*[10]*, D. S. Mandell*[11] *and C. Kasari*[2]*, (1)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Drexel University, Phialdelphia, PA, (4)University of California, Davis, Sacramento, CA, (5)University of Pennsylvania, Philadelphia, PA, (6)Maternal and Child Health Bureau, Office of Epidemiology and Research, Health Resources and Services Administration, Rockville, MD, (7)Carnegie Mellon University, Pittsburg, PA, (8)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (9)University of Rochester Medical Center, Rochester, NY, (10)University of California at Davis, Sacramento, CA, (11)Center for Mental Health, University of Pennsylvania, Philadelphia, PA*

Background: Parents and providers face challenges preparing children with ASD for school transitions (Boyd, McDowall, & Cooper, 2002; Tehee, Honan, & Hevey, 2009). Social relationships among a child's key supporters could provide important resources to improve transition success. Social network analysis offers powerful ways to examine dimensions ofthese relationships such as sharing and problem-solving (Fischer 1982; Rodrique et al 1990; Laumann and Pappi 1976; Breiger 1981). Network approaches have been applied in studies of health or health behavior (Bearman & Moody 2004; Bearman, Moody & Stovel 2004; Christakis & Fowler 2007, 2008; Coleman, Elihu & Menzel 1966) as well as health information-seeking (Colon-Ramos et al 2009) and communication and decision-making among health care personnel (Creswick, Westbrook & Braithwaite 2009; Fattore et al 2009; Scott et al 2005). Our study tests associations between structural dimensions of social relationships and transition success for children with ASD, thereby informing systematic attempts to improve school transitions for these children.

Objectives: Use ego-centric social network techniques to test the association between the perception of transition success and different types of social relationships, including instrumental relationships such as problem-solving networks and affective relationships such as trust networks. We test the hypothesis that problem solving networks and trust networks among home/school/community care providers are associated with perceptions of transition success.

Methods: 47 participants completed social network interviews, conducted 6 weeks before the end of the child's school year at the old school, including 8 parents and 39 providers. We interviewed key participants using the **SoDI: The Social Dynamics of Intervention Measure (**McGhee Hassrick et al 2018; McGhee Hassrick and Carley 2015), where each participant reported frequency of problem solving and degree of trust for each person on the team roster. Using ORA network analysis software (Carley et al 2004), we computed egocentric problem solving and trust measures for each participant, including **in-degree** (# of team members who seek out the participant), **out-degree** (# of team members that the participant seeks out) and **eigenvector centrality** (degree of connectivity that the participant had with well-connected team members). Participants also rated **perceived transition success** on a 5-point Likert scale, where 1 = not successful and 5 =very successful. We used OLS regression to test associations between our outcome measure of perceived transition success and our egocentric network predictor variables.

Results: Perceived transition success was positively and modestly associated with out-degree centrality in trust networks, positively and significantly associated with eigenvalue centrality in trust networks and negatively associated with in-degree centrality in trust networks. It was also positively associated with indegree, outdegree and eigenvector centrality in problem solving networks, but these associations were not significant.

Conclusions: Trust was an important predictor for transition success. When participants trusted team members who themselves where highly trusted, their perception of the child's transition success was significantly higher. This finding suggests that building trust for key leaders on a child's team might increase the perception of transition success.

Background:

A normative female advantage in social cognition skills has been proposed to contribute to the reduced risk of females to develop autism spectrum disorder (ASD) (Baron-Cohen et al., 2005; Christov-Moore et al., 2014). However, it is unclear if differences in brain structure related to social cognition exist between the sexes, and if such potential differences are associated with autistic trait severity. Further, studies on social cognition in ASD have often used tasks with low ecological validity, that are not challenging enough for higher functioning subjects (Dziobek et al., 2006).

Objectives:

The present study therefore aimed to investigate the relationship between brain structure and social cognition skills, assessed with a more complex, ecologically valid, social cognition task, as well as autistic traits, in males and females along the continuum of ASD. By using a co-twin control design, we were able to control for familial confounding factors (e.g. age, socio-economic status, etc.).

Methods: From the Roots of Autism and ADHD Twin Study Sweden (RATSS) 57 twin pairs (24 female and 33 male pairs), mean age 17.57 (range 12.52 - 23.69), completed the movie for the assessment of social cognition (MASC). In addition, autistic traits related to social cognition difficulties were assessed with a subscale from the parent-report Social Responsiveness Scale-2 (SRS-2). Twin pairs were either discordant or concordant for ASD, discordant or concordant for other neurodevelopmental disorders, or concordant for neurotypical development. Surface based morphological estimates including cortical surface, thickness and volume were computed from T1 anatomical images. Across and within-pair associations were calculated between social cognition and anatomical structure in the cerebral social network.

Results:

Females displayed better social cognition skills (MASC) compared to males, but there was no sex difference in the amount of autistic traits associated with social cognition difficulties (SRS-2). After controlling for shared factors within twin pairs, overall autistic traits predicted reduced social cognition skills only in males. In line with this, only in males were decreased social cognition skills (MASC) associated with increased thickness of the left inferior frontal, insula, mid temporal and right fusiform gyri. These associations between social cognition skills and brain structure were largely replicated in a subsample consisting of ASD discordant pairs (6 female and 8 male pairs). In contrast, autistic traits (related to social cognition difficulties (SRS-2)) were associated with reduced volume and surface area of most regions of interest only in females.

Conclusions: When controlling for familial factors, variation in social cognition skills was associated with brain structure mostly in males, while autistic traits related to social cognition difficulties were associated with brain structure only in females. Our findings therefore point at potential differences between males and females in autism phenotype and associated underlying neural structure. Finally, the results highlight the power of using a co-twin control design to detect subtle associations between brain structure and behavior, and suggest the importance of non-shared environmental factors in the relationship between neuroanatomy and social cognition skills.

1:57 **194.002** Sex Differences in Structural Brain Development Underlying a Female Protective Effect

***D. Yang**[1,2], A. Jack[1], P. E. Ventola[3], E. H. Aylward[4], M. Dapretto[5], D. Geschwind[6], J. S. Duncan[7], G. L. Wallace[1], S. J. Webb[8], S. Y. Bookheimer[5], L. Kenworthy[9], C. Torgerson[10], Z. Jacokes[10], C. A. Nelson[11], J. Van Horn[10], T. Girls' Neurogenetics Network Team[1] and K. Pelphrey[1], (1)The George Washington University, Washington, DC, (2)Children's National Medical Center, Washington, DC, (3)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Seattle Children's Research Institute, Seattle, WA, (5)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (6)University of California, Los Angeles, Los Angeles, CA, (7)Biomedical Engineering/Radiology, Yale University, New Haven, CT, (8)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (9)Children's National Health System,* *Washington, DC, (10)University of Southern California, Los Angeles, CA, (11)Boston Children's Hospital, Boston, MA*

Background: Autism Spectrum Disorders (ASD) disproportionately affect males over females. Our NIH Autism Center of Excellence Girls' Neurogenetics Network has contributed to understanding this bias at the levels of gene structure and expression, neural dynamics, brain function, and connectivity. The skew may be explained in part via mechanisms that confer a Female Protective Effect (FPE), combined with normative sexually dimorphic brain development, environmental factors, and potential measurement biases. This work is important because characterizing the FPE may help illuminate and treat ASD in both sexes.

Objectives: We sought to model and evaluate cortical thickness in males and females with ASD and age-, sex-, and cognitive-ability matched typically-developing (TD) comparison participants.

Methods: The sample included 219 children and adolescents (age: M = 13.01y, SD = 2.91y, range = 8.03-17.99y; IQ: M = 107.50, SD = 17.87, range = 75-167) recruited from four research sites (Yale, Harvard, UCLA, Seattle). There were 54 ASD females, 52 TD females, 59 ASD males and 54 TD males. The four groups were well-matched on age and IQ. Females (F) and males (M) with ASD were well-matched on ASD symptom severity, language ability and adaptive behaviors. F-ASD and F-TD were well-matched on intracranial volume (ICV), so were M-ASD and M-TD. All participants underwent a T1-weighted structural scan. Cortical thickness was estimated using FreeSurfer v6.0.0 and fwhm=15mm. Quality of the structural MRI images were independently rated by two researchers, blind to group membership; 30 subjects (6 F-ASD, 5 F-TD, 17 M-ASD, 2 M-TD) exhibiting obvious head motion were discarded. Age was centered before entered into analysis. Results were thresholded at $Z>1.96$ (vertex-level) and $p<.05$ (cluster-level) (two-sided), while site, IQ, and ICV were included as covariates of no interest.

Results: The analysis showed that across all participants, as expected, there were widespread age-related reductions in cortical thickness during this developmental epoch. In males, the whole-brain analysis revealed a significant Age × Diagnosis interaction localized to the right pSTS and nearby regions as outlined in **Figure 1**. However, in girls, there were no surviving regions across the whole brain showing a significant Age × Diagnosis interaction, while the Age × Diagnosis interaction in the outlined region was not significant in girls, $p=.21$. Finally, the 3-way Age × Diagnosis × Sex interaction effect in the outlined region was significant, $p=.04$, partial $\eta^2 = .024$. The scatterplots are also presented for this region.

Conclusions: Consistent with prior, published reports, males with ASD relative to same-sex TD exhibit accelerated age-related cortical thinning specifically in the right pSTS region during late childhood and adolescence. However, this atypicality is not present in girls with ASD. These findings suggest evidence for one of the developmental brain differences underlying the FPE in ASD.

2:09 **194.003** Multi-Class Pattern Classification Discriminates Young Males and Females with Autism Spectrum Disorder Based on Cortical Morphology

H. Hosseini[1], *A. Annapureddy*[1], *L. Libero*[2], *J. K. Lee*[2], *N. Sharma*[3], *C. C. Coleman*[4], *D. G. Amaral*[2], *F. Hoeft*[5] *and C. W. Nordahl*[2], *(1)Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (2)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (4)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA, (5)Psychiatry, UCSF School of Medicine, San Francisco, CA*

Background: Autism spectrum disorder (ASD) is diagnosed much more frequently in males than in females. One prevailing theory for explaining the male bias in ASD is the multifactorial liability model, which suggests that multiple liability factors shift the vulnerability threshold for ASD higher in females, such that a smaller proportion of females reach clinical diagnosis. One prediction from this model is that females with ASD will exhibit a higher liability of neural alterations and will deviate further from typically developing (TD) females than their male counterparts. There is growing evidence supporting distinct pattern of neural alterations in females with ASD in older individuals, but studies of very young children are lacking.

Objectives: We utilized cortical surface area, thickness, and volumetric measurements to evaluate within- and between-sex and diagnosis differences in a large cohort of preschool-aged children with ASD and TD controls.

Methods: We acquired structural T1-weighted MRIs in 213 children with ASD (150 male, 63 female) and 101 age-matched TD controls (54 male, 47 female). Mean age at time of MRI acquisition was 39 months. Cortical reconstruction and volumetric segmentation were performed within FreeSurfer v5.1.0. Cortical gray matter volumes, cortical thicknesses and surface areas were extracted for 68 gyral regions (Desikan-Killiany atlas). A multi-class linear discriminant model was used to identify patterns of brain regions that discriminate between sex and diagnosis (ASDf, ASDm, TDf, TDm). The validity of the model was tested using a leave-four-out cross-validation (leave one sample from each and every of the four groups out) to avoid overfitting with biased sample size. This process also allowed the training and test cases to remain independent. Finally, permutation analysis was performed to empirically determine if the obtained classification accuracy was significantly greater than chance. We report: (1) classification accuracy of test sets, (2) feature weights that contributed to the classification, and (3) the overlap and non-overlap in brain regions across different comparisons.

Results: Our preliminary results suggest that the multi-class linear discriminant model could achieve an accuracy of 47.2% which was significantly higher than chance (p = 0.001, null accuracy = 27.4%). Interestingly, the two most-discriminant vectors for the multiclass model distinguished sex and diagnosis, respectively (Figure 1). Regions specific to diagnosis comparison (ASD vs. TD) included regions in neural systems related to understanding mental states of others, expressive language and reception of facial communication (right temporal pole, bilateral lateral occipital, bilateral fusiform) as well as bilateral transverse temporal, left entorhinal, and superior parietal lobule. Regions specific to sex comparison included right pars triangularis, posterior cingulate, superior temporal sulcus, and left lingual gyrus. Regions overlapping across sex and diagnosis comparison included bilateral middle frontal gyurs, left rostral anterior cingulate, precuneus, and inferior temporal gyri. Surface area measures contributed the most to the classification.

Conclusions: These preliminary data suggest that females and males with ASD have patterns of cortical alterations that are distinguishable from TD males and females. In addition, neural patterns of diagnostic differences are more pronounced in females than in males, providing support for the multifactorial liability model.

2:21 **194.004** Genetic and Environmental Influences on Cortico-Striato-Thalamo-Cortical Circuits in Twins with Autism

J. P. Hegarty[1], *M. Gu*[2], *D. M. Spielman*[2], *S. C. Cleveland*[1], *J. F. Hallmayer*[1], *L. C. Lazzeroni*[1], *M. M. Raman*[1], *T. W. Frazier*[3], *J. M. Phillips*[1], *A. L. Reiss*[1] *and A. Y.*

Hardan[1], (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Radiology, Stanford University, Stanford, CA, (3)Autism Speaks, New York, NY

Background:

Cortico-striato-thalamo-cortical (CSTC) circuits are involved with carrying out goal-directed behaviors and disruption of these pathways is associated with aberrant behaviors, such as obsessive thinking and repetitive behaviors. The structures that comprise these circuits include cortical (orbitofrontal (OFC) and anterior cingulate (ACC) cortices), striatal (caudate, putamen, and globus pallidus), and thalamic regions. Although limited, investigations of individuals with autism spectrum disorder (ASD) support a potential relationship between abnormalities in these regions and restricted and repetitive behaviors (RRB).

Objectives:

The goal of the current investigation was to examine CSTC regions in twins with and without ASD to determine whether abnormalities in these circuits are related with RRB symptoms and associated with genetic or environmental influences.

Methods:

Data were acquired as part of a large-scale neuroimaging study of same-sex twin pairs that included monozygotic (MZ) and dizygotic (DZ) twins with ASD and typically-developing (TD) control twins. Measures of autism-related symptom severity included the Social Responsiveness Scale (SRS) and Repetitive Behavior Scale-Revised (RBS-R). A structural T1-weighted spoiled grass gradient recalled (SPGR) 3D MRI was acquired on a 3 Telsa GE scanner and cortical reconstruction/segmentation was performed using FreeSurfer. Morphometric differences between groups were examined with mixed effects models and correlations between regional measurements and RRB symptoms were assessed. Additionally, intra-class correlations (ICC) were compared between MZ and DZ twin pairs. ACE and AE models for broad sense heritability (a^2=additive genetics) and environmental influences (c^2=shared family environment, e^2=unique environment) were then calculated to provide an estimate of the proportion of variation associated with genetic/environmental factors.

Results:

In this preliminary analysis, valid segmentations were available from 48 twin pairs with ASD (21 MZ/27 DZ) and 33 TD pairs (19 MZ/14 DZ). The ASD and TD samples included children and adolescents (age range: 6-15 years) that were adequately matched as there were no group differences in age or gender, p>0.05. Examining volumes of CSTC regions, the largest differences were found in striatal regions with larger volumes in ASD compared to TD, particularly the putamen (M_{ASD}= 6350.32,SD= 769.94; M_{CTRL}= 6040.69,SD= 589.86; p<0.001). Within twin pairs discordant for ASD, there were additional indications of volumetric abnormalities with larger volumes in cortical regions, such as the ACC (M_{ASD}= 2761.50,SD= 524.31; M_{CTRL}= 2562.67,SD= 575.35; p<0.007), but smaller volumes of thalamic regions, (M_{ASD}= 8174.92,SD= 1232.92; M_{CTRL}= 8837.24,SD= 863.91; p<0.007). Additionally, CSTC volumes were associated with RRB symptoms (e.g., OFC and RBS-R Restricted Behaviors, r=0.29, p=0.009). Finally, genetic factors accounted for the largest proportion of variance in the size of striatal and thalamic regions (~0.60-1.00) but exerted less influence on some cortical structures (~0.20-1.00), with potentially relevant differences between twins with ASD and controls.

Conclusions:

Consistent with previous reports, preliminary data from this investigation indicate that children and adolescents with ASD exhibit volumetric abnormalities in CSTC circuits, which may be associated with RRB symptom presentation. More importantly, comparisons between twin pairs indicate that genetic susceptibility for ASD, as opposed to environmental factors, likely influence abnormalities in striatal and thalamic structures but that environmental factors may exert more influence on prefrontal cortex abnormalities.

2:40 **195.001** Reduced Ratio of Inner to Outer Surface Area of the Brain in Autism Spectrum Disorders (ASD)

***C. Mann**[1], A. Bletsch[1], D. S. Andrews[2], E. Daly[3], C. M. Murphy[3], M. Gudbrandsen[3], D. G. Murphy[4] and C. Ecker[1,3], (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe-University Frankfurt am Main, Frankfurt, Germany, (2)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (3)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:

The neuroanatomy of ASD is both complex and multifaceted, affecting multiple aspects of the neural architecture *in vivo* (Ecker, 2017). Among others, neuroanatomical abnormalities in ASD also include differences in cortical folding (e.g. Wallace et al., 2013; Ecker et al., 2016, Schaer et al., 2013). While several different mechanisms have been suggested to mediate cortical folding (for review see Lewitus et al., 2013), there is evidence to suggest that local gyrification is driven by a differential expansion of upper vs. lower neural layers (Richman et al., 1975; Kriegstein et al., 2006). This hypothesis is also of relevance to recent genetic investigations suggesting that ASD-related genes are not equally expressed across all cortical layers, but predominantly affect the superficial cortical layers (e.g. Parikshak et al., 2013).

Objectives:

The present study therefore aimed to establish whether the ratio of the inner to outer surface area ($R_{outer:inner}$) of the brain significantly differs in ASD individuals from neurotypical controls during childhood and adolescence.

Methods:

73 right-handed males with ASD (diagnosed using ADI-R (Lord et al., 1994)), and 75 neurotypical controls, aged 8-25 years were recruited and assessed at the Institute of Psychiatry, Psychology, and Neuroscience, King's College, London. Both groups were matched for age, handedness, and full-scale IQ. For all 148 participants, high-resolution structural T1-weighted volumetric images were acquired.

Cortical surface models were derived using the FreeSurfer image analysis suite (http://surfer.nmr.mgh.harvard.edu/). The $R_{outer:inner}$ was calculated as the ratio of inner (i.e. white matter) to outer (i.e. grey matter) surface area. Parameter estimates for $R_{outer:inner}$ were estimated by regression of a general linear model (GLM) at each vertex with (1) group as categorical fixed-effects factor, (2) linear age, as well as an age-by-group interaction, and (3) FSIQ as continuous covariate. Corrections for multiple comparisons across the whole brain were performed using random-field theory (RFT)-based cluster-corrected analysis for non-isotropic images using a p=0.05 (two-tailed) cluster significance threshold.

Results:

There were no significant group differences in age [$t(146) = -1.69$, $p = 0.09$], or FSIQ [$t(146) = 1.77$, $p = 0.08$] between ASD individuals and controls. We found that $R_{outer:inner}$ was significantly decreased in ASD individuals relative to controls in several clusters, which predominantly included prefrontal and temporal regions. Moreover, we observed significant age-by-group interactions in the (1) right middle temporal gyrus, (2) left anterior cingulate cortex, and in the (3) right superior cortex (RFT based cluster corrected, $p<0.05$). In addition, ASD individuals also had significantly reduced vertex-wise measures of absolute inner and outer surface area compared to healthy controls.

Conclusions:

Our findings suggest that a differential expansion of the inner and outer surface area in the brain of individuals with ASD may mediate the differences in local gyrification that have previously been reported in the condition. The $R_{outer:inner}$ might also be used to guide future studies into the genetic and molecular underpinnings of ASD, and for the stratification of ASD individuals into biologically more homogeneous subgroups.

2:52 **195.002** Examining Associations between Brain Morphology and Social Function in ASD, ADHD, OCD, and Typical Development Using Machine Learning: Analysis of Pond Network Data

A. Kushki[1,2], *M. Komeili*[3], *S. Panahandeh*[4], *E. Anagnostou*[5] *and J. P. Lerch*[6], *(1)Bloorview Research Institute, Toronto, ON, Canada, (2)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, (3)University of Toronto, Toronto, ON, Canada, (4)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Vaughan, ON, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada*

Background: There is significant variability in biology and behavior *within* the autism spectrum. At the same time, autism spectrum disorder (ASD) shares biological and behavioral traits with other neurodevelopmental disorders including attention deficit/hyperactivity disorder (ADHD) and obsessive compulsive disorder (OCD). This challenges existing diagnostic categories and motivates a diagnosis-agnostic and data-driven approach to characterizing variability across the autism spectrum and related neurodevelopmental disorders.

Objectives: The objectives of this study were two-fold: 1) characterize variability in brain-behaviour associations across ASD, ADHD, OCD, and typical development (TD) using a data-driven and diagnosis-agnostic approach, and 2) examine whether or not diagnostic labels are associated with distinct brain-behaviour patterns.

Methods: Data from a sample of 218 participants in the POND Network studies were used for analysis (n_{ASD}=104, age:11.3±2.7; n_{ADHD}=62, age:10.9±2.5; n_{OCD}=35, age:12.1±2.3; n_{TD}=17, age:10.9±2.7). Brain data included cortical thickness measurements from 76 regions of the brain obtained using the CIVET pipeline, and corrected for total brain volume, age, and site. Behavioural data were total scores on the Social Communication Questionnaire (SCQ). Analyses were performed using a novel machine learning pipeline comprising two steps: 1) a feature selection step, using sequential feature forward selection, to determine the brain regions whose variability best aligned with that of the behavioural data, and 2) discovery of clusters that were aligned across brain and behaviour data using co-regularized multi-view spectral clustering. To ensure stability of the found patterns, the analyses were run on 500 random partitions of the data, each including 90% of the participants. Only participants who were assigned to the same cluster over 50% of the time (significantly higher than chance) were considered connected in the final analysis.

Results: The results revealed a complex pattern of brain-behaviour association, characterized by a many-to-many mapping. Five groups emerged based on clustering. Cluster boundaries were not crisp for groups 2-5. Groups generally contained participants from all diagnostic categories (% dx (ASD:ADHD:OCD:TD): group 1 - 37:3:6:0, group 2- 23:19:9:6, group 3- 35:18:6:6, group 4- 4:29:34:29, group 5- 2:31:46:59). The groups differed significantly on SCQ scores and IQ (p<0.0001), but not age. Group 5 had the lowest SCQ score and the highest IQ, whereas group 1 had the highest SCQ and lowest IQ. There were also significant group differences in cortical thickness in the left lingual gyrus and the right precuneus, the two regions that best aligned the brain and behavioural data (p<0.0001). Three groups with the largest proportion of ASD participants (35%, 37%, and 23%) showed varying SCQ scores (16.5+4.4; 26.9+3.1; 13.9+4.7) and cortical thickness values (Lingual gyrus (z-score): 0.4+0.1; -0.2+1.0;-0.7+0.7).

Conclusions: Examining brain and behavioural data from a sample of children with neurodevelopmental disorders, this study revealed a complex and many-to-many association among cortical thickness and social function measured by the Social Communication Questionnaire. The results suggests that brain-behaviour patterns are shared among ASD and ADHD, OCD, and typical development, supporting biological and behavioural overlap among these disorders, as well as a a dimensional model of traits that extends into typical development.

3:04 **195.003** Neurite Orientation Dispersion and Density Imaging in Autism Spectrum Disorders

D. C. Dean[1], *J. Villaruz*[1], *A. Freeman*[1], *N. Adluru*[1], *K. Kellett*[1], *K. Kane*[1], *J. B. King*[2], *M. B. Prigge*[2], *B. A. Zielinski*[2], *J. S. Anderson*[3], *J. Taylor*[2], *S. Schrodi*[4], *N. Matsunami*[2], *E. Bigler*[5], *M. Leppert*[2], *N. Lange*[6], *J. E. Lainhart*[1] *and A. L. Alexander*[1], *(1)University of Wisconsin - Madison, Madison, WI, (2)University of Utah, Salt Lake City, UT, (3)Radiology and Imaging Sciences, University of Utah, Salt Lake City, UT, (4)Marshfield Clinic Research Institute, Marshfield, WI, (5)Brigham Young University, Provo, UT, (6)McLean Hospital, Cambridge, MA*

Background: Diffusion tensor imaging (DTI) is an integral neuroimaging technique to assess white matter microstructure and has been influential to the study of white matter alterations in ASD. However, one of the major limitations of DTI is that the quantitative measures estimated via this technique are inherently non-specific; that is, a variety of microstructural or biochemical processes could lead to similar DTI parameter estimates. As a result, the ability to identify specific microstructural features using DTI is limited. Biophysical modeling techniques, such as neurite orientation dispersion and density imaging (NODDI), may improve the level of microstructure specificity available and thus could provide new insights into the microstructural changes observed in ASD.

Objectives: We sought to investigate, for the first time, white matter microstructural differences between individuals with and without a ASD diagnosis using the NODDI imaging technique.

Methods: Participants for this study consisted of 108 individuals between 5 and 42 years of age, 41 of which were diagnosed with ASD. A threeshell diffusion weighted imaging (DWI) protocol was acquired with b-values of 350, 800, and 2000 s/mm^2 at 63 non-collinear diffusion encoding directions on a 3.0 Tesla GE MR750 scanner. Following acquisition, DWI images were corrected for eddy-current distortions and head motion and subsequently fit to the NODDI model, yielding parameter maps of intracellular and isotropic volume fractions (v_{IC}, v_{ISO}, respectively), and orientation dispersion index (ODI). These maps were nonlinearly aligned to a population specific template using DTI-TK, while permutation testing adjusted by age and a threshold free clustering approach was used to examine voxelwise differences between the ASD and typical development (TD) groups.

Results: Comparison of NODDI measures yielded widespread differences between the ASD and TD groups (Fig. 1). Specifically, TD controls were observed to have higher v_{IC} within regions including the internal capsules, thalamus, brain stem and pons ($p<0.05$, TFCE-adjusted). Differences in ODI were mixed. For example, controls were observed to have higher ODI with deep white matter areas, such as the internal capsules and brain stem, while the ASD group was observed to have higher ODI in more peripheral white matter, including the genu of the corpus callosum, and regions of parietal white matter ($p<0.05$, TFCE-adjusted). Isotropic volume fraction was observed to be higher in the ASD group extensively across the brain ($p<0.05$, TFCE-adjusted).

Conclusions: Our preliminary findings suggest a reduction of v_{IC} and ODI in regions of the internal capsules, thalamus and brain stem within the ASD group, while having increased ODI and v_{ISO} in more widespread brain regions. These findings agree well with the current DTI literature that describe alterations of white matter microstructure associated with ASD, while also suggesting the possibility that these white matter alterations may stem from alterations to the neurite architecture, such as decreased neurite density and/or increased white matter angular dispersion. Future analyses will investigate the age-related relationships of these neurobiological changes and the behavioral processes that may be involved with these alterations.

3:16 **195.004** Towards Personalized Medicine in Autism Diagnosis: Anatomical Abnormalities Analysis Using a Deep Learning Based Approach

O. Dekhil[1], *M. Ghazal*[2], *A. Shalaby*[3], *A. Switala*[4], *A. S. El-Baz*[4], *A. Khalil*[5] *and G. Barnes*[6], *(1)Bioengineering, university of Louisville, Louisville, KY, (2)Electrical and Computer Engineering, Abu Dhabi University, Abu Dhabi, United Arab Emirates, (3)Bioengineering, University of Louisville, Louisville, KY, (4)University of Louisville, Louisville, KY, (5)Information Technology and Computer Science, Abu Dhabi University, Abu Dhabi, United Arab Emirates, (6)University of Louisville School of Medicine, Louisville, KY*

Background: Background. Autism spectrum disorder (ASD) is a neurodevelopmental syndrome that affects both communication and social interaction. Although there is no well-defined cause of ASD, there are many proposed theories and hypotheses aiming to explain ASD causes; for example structural abnormalities, connectivity abnormalities and functional activation are widely studied.
Objectives: In this study data from structural MRI (sMRI) was used to identify anatomical characteristics distinguishing ASD from typically developing (TD) subjects in a demonstration of Sight software for computer-assisted diagnosis (CAD) of ASD, developed at our laboratory.

Methods: The Sight processing pipeline begins by isolating the brain from a T1-weighted MRI using Fsl Bet with post-processing to validate the result. The test brain is aligned with a library of previously segmented data, which are used to derive prior shape information to guide the segmentation of the cerebral cortex. A triangulated mesh of the cortical surface is output. Mesh vertex coordinates are re-parameterized in terms of spherical polar coordinates in order to analytically approximate the surface by spherical harmonic series. Three shape descriptors are obtained per Brodmann area: (a) truncation error as a function of order of spherical harmonic approximation, (b) distribution of mean curvature, and (c) distribution of Gaussian curvature. Features are input to a stacked autoencoder, producing higher-order representations, which are input to a second network with a softmax classification layer, trained to recognize features consistent with ASD on a local level. The higher-order representations from all areas are also concatenated for input to another classifier to obtain the overall decision. The Sight classifier was trained and tested using scans of 202 individuals downloaded from the National Database for Autism Research (NDAR), 78 of whom were diagnosed with ASD.

Results: ASD and TD subgroups both ranged in age from 7 to 17 years, and had similar proportions of male and female individuals. Using two-fold cross validation the Sight software correctly classified 78 of 78 ASD cases and 90 of 124 TD cases. Some brain regions were found to have significant influence on classification. Using supramarginal gyrus, pars triangularis, or inferior prefrontal gyrus, to the exclusion of all other regions, produced classifiers with 76%, 77%, and 79% accuracy, respectively. The most influential areas are highly correlated with functional deficits in autism, such as speech and syntax processing and emotional responses.

Conclusions: Sight is an important step towards personalized medicine, where each localized brain region is studied separately to allow better way to allocate each subject on the autism spectrum and enables better prediction to the affected brain functionality based on the affected areas, but expansions to the framework are already in progress to: (1) incorporate dwMRI- and fMRI-based descriptors into a multimodal CAD system that can better resolve ASD endophenotypes and (2) distinguish ASD from other disorders such as childhood epilepsy.

Tech demo. There will be live demonstration of Sight CAD software. All procedure steps from segmentation to report generation will be performed, and intermediate output will be available for inspection.

1:45 **196.001** Long-Term Efficacy and Safety of Pediatric Prolonged-Release Melatonin for Insomnia in Children with Autism Spectrum Disorder

A. Maras[1], *B. A. Malow*[2], *T. Nir*[3], *N. Zisapel*[3] *and P. Gringras*[4], *(1)Yulius Academy, Yulius Mental Health Organization, Barendrecht, Netherlands, (2)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN, (3)Neurim Pharmaceuticals, Tel Aviv, Israel, (4)Children's Sleep Medicine, Evelina London Children's Hospital, Guy's and St Thomas', London, United Kingdom*

Background: A recent double-blind randomized placebo-controlled study demonstrated 3-months' efficacy and safety of novel pediatric-appropriate prolonged-release melatonin minitablets (PedPRM; 2/5 mg) vs. placebo in children and adolescents with Autism Spectrum (ASD) and Neurogenetic Disorders (NGD) suffering from insomnia.

Objectives: To investigate the long term maintenance of PedPRM efficacy, safety and dosing in patients receiving 1 year of study medication.

Methods: A prospective 9-months open-label follow up study of efficacy and safety of PedPRM in community dwelling patients with ADS/NGD. Sleep measures included the validated caregivers' Sleep and Nap Diary (SND) and Composite Sleep Disturbance Index (CSDI).

Results:

95 patients aged 2-17.5 years [mean age 9 ± 4.24, 74.7% males] who completed the 3 months double-blind trial (51 from PedPRM arm and 44 from the placebo arm) received open-label PedPRM at final 2/5 mg dose with optional dose adjustment to 2-10 mg/day after 3 months. By the end of the follow up period, 41 of the PedPRM randomized group completed 1 year of PedPRM and 38 of the placebo randomized group completed 9 months of PedPRM. The improvements in total sleep time (TST), sleep latency (SL) and duration of uninterrupted sleep (longest sleep episode) seen in the double blind-phase were maintained throughout the follow up period with mean improvement of 44.35 minutes in TST($p=0.002$), -41.36 minutes in SL ($p<0.001$) and 78.63 minutes in uninterrupted sleep ($p<0.001$) over baseline. In addition, CSDI measured sleep disturbance and parent satisfaction of their child's sleep patterns, were significantly improved ($p<0.001$ for both). There was no evidence of tolerance to PedPRM. Overall 75% of patients in the 9 months follow up had clinically relevant improvement in TST of 45 minutes or more, or reduction in sleep latency of 15 minutes or more, or both, compared to 69% by the end of the DB phase. Of the 71 completers who provided SND data, 53 (75%) achieved an overall improvement of one hour or more in TST, SL or both, over baseline. The average daily dose was 5.3 mg (range 2-10 mg). PedPRM was generally safe; daytime somnolence was more commonly reported treatment-related adverse event, with PedPRM than placebo.

Conclusions:

PedPRM is an effective and safe treatment option for long term treatment of children with ASD suffering from insomnia.

1:57 **196.002** Antidepressants Modulate Brain Activation Differently in Autism Compared to Controls

R. H. Wichers[1], *J. Findon*[2], *V. Giampietro*[3], *V. Stoencheva*[1], *C. M. Murphy*[1], *G. M. McAlonan*[2], *C. Ecker*[4], *K. Rubia*[5], *D. G. Murphy*[6] *and E. Daly*[1], *(1)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Neuroimaging, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (4)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe-University Frankfurt am Main, Frankfurt, Germany, (5)Department of Child and Adolescent Psychiatry, King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (6)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:

Individuals with autism spectrum disorder (ASD) often suffer from psychiatric comorbidities such as anxiety and depression. Current treatments for these conditions are identical to those in neurotypical populations and include selective serotonin reuptake inhibitors (SSRIs). The effectiveness of SSRIs in ASD is controversial as; 1) limited treatment response and increased adverse events have been reported (Williams et al. 2013), and 2) disruptions in the serotonergic system have been widely described. Furthermore, we demonstrated that reducing serotonin by acute tryptophan depletion normalizes brain function abnormalities in ASD (Daly et al. 2014). Therefore, treatment with an existing drug that reduces serotonin - such as the selective serotonin reuptake enhancer (SSRE) tianeptine - may be more appropriate. Furthermore, it has been suggested that differences in the serotonergic system may underlie altered neurocognitive function in ASD. Hence, investigating the modulating role of serotonergic antidepressants on neurocognitive functions in ASD may help to explain the differences in treatment response, which could lead to better tailored interventions.

Objectives:

To test the effect of the SSRI citalopram and the SSRE tianeptine, on sustained attention and inhibitory networks in ASD.

Methods:

Nineteen right-handed adult males with ASD (diagnosed using the ADI-R and ADOS) and 19 typically developed controls (TD) were included. Pharmacological magnetic resonance imaging (phMRI) was used to compare brain activity during a sustained attention task and a Go/No-Go task under an acute dosage of 20 mg citalopram, 12.5 mg tianeptine and placebo in a randomized, double-blind, crossover procedure. The phMRI data were analyzed using a nonparametric approach (c.f. http://brainmap.it) and significance was defined as $p <.05$ (corrected for multiple comparisons).

Results:

There were significant interaction effects of BOLD signal response between drug status (placebo, citalopram and tianeptine) and group (TD, ASD) during both the sustained attention and Go/No-Go task. During sustained attention both citalopram and tianeptine significantly downregulated brain activation in the right thalamus in the control group. In contrast, both drugs upregulated brain activation in the right thalamus in individuals with ASD. During response inhibition both citalopram and tianeptine decreased brain activation in the anterior cingulate cortex in the control group whereas both drugs increased brain activation in ASD.

Conclusions:

Our findings support the evidence that antidepressant treatments commonly used in neurotypical populations may not be as 'translatable' to individuals with ASD as currently assumed. Thus, pharmacological interventions affecting the serotonergic system need to be tested specifically in the ASD population.

2:09 **196.003** Bumetanide to Ameliorate Hyperexcitable Behavior in Tuberous Sclerosis Complex

D. M. van Andel[1], *C. Vlaskamp*[2], *J. J. Sprengers*[1], *F. E. Jansen*[3], *B. Oranje*[2] *and H. Bruining*[4], *(1)Brain Center Rudolf Magnus, Department of Psychiatry, UMC Utrecht, Utrecht, Netherlands, (2)Department of Psychiatry, Brain Center Rudolf Magnus, NICHE Lab, University Medical Center Utrecht, Utrecht, Netherlands, (3)Department of Child Neurology, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, Netherlands, (4)Brain*

Centre Rudolf Magnus, Amsterdam, Netherlands

Background:
Selective treatment in Autism Spectrum Disorder (ASD) may be based on genetic or molecular information. Here we present a rational treatment for tuberous sclerosis complex (TSC), a monogenetic disorder strongly associated with ASD. Preclinical studies have identified signs of excitatory $GABA_AR$ transmission in tubers and perituberal cortex of TSC patients indicating disturbed chloride homeostasis. These imbalances may be a common mechanistic pathway and underlie the observed (hyper)excitability in these neurodevelopmental disorders. Bumetanide, a selective NKCC1 antagonist, may enhance GABAergic transmission by correcting intracellular chloride concentration. We present results of an open-label trial testing the effect of bumetanide on behavior, cognition, resting state EEG and event related potentials (ERP) in a sample of children with TSC with and without formal ASD diagnosis.

Objectives:

Open label trial testing bumetanide to improve behavioral, cognitive and neurophysiological adaptation in TSC patients.

Methods:

Add-on open-label trial in which 12 TSC patients (aged 8-21) were treated with bumetanide for 3 months, followed by a 1-month wash-out phase. Treatment effect was evaluated by a broad range of behavioral and cognitive endpoints, including autism symptom questionnaires. Novel advanced electroencephalography (EEG) markers were where possible used to objectify treatment effect and to identify candidate prognostic biomarkers.

Results:

An overall beneficial effect on behavioral functioning was obtained, that could be substantiated by individual EEG parameters in several cases. Improvements were analyzed in relation to EEG markers of hyperexcitability and sensory processing abnormalities.

Conclusions:

(Add on) bumetanide treatment is a novel treatment consideration to improve daily functioning for patients with TSC. Improvement in neural imbalances and sensory reactivity may indicate overlap in common treatment targets between TSC and idiopathic ASD.

2:21 **196.004** A RCT of Tideglusib Vs Placebo: Data from the Pond Network

E. Anagnostou[1], *R. Nicolson*[2] *and T. Bennett*[3], *(1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)University of Western Ontario, London, ON, Canada, (3)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA*

Background:
Molecular pathways and neuropathology findings implicated in ASD suggest abnormalities in postsynaptic elements and postsynaptic protein synthesis among others. Several rare but highly penetrant mutations recently associated with ASD have targets in the postsynaptic space, with certain pathways being modulated by GSK-3 activity (e.g. ERK, mTOR, Akt)

Tideglusib is a GSK-3β inhibitor. To consider the utility of tideglusib for a heterogeneous disorder such as ASD, we approach the problem by examining its potential effects on single gene syndromes that may be associated with ASD, in addition to examining pathways highlighted by the genomic approach. Pharmacological agents that can deplete GSK-3β such as Tideglusib have been shown to rescue the phenotype of the Fragile X – FMR1 knockout transgenic mouse. Rescued or improved domains included learning and memory, hyperactivity, anxiety and fear conditioning, as well as repetitive behaviors (Franklin et al., 2013) In addition, Tideglusib is brain penetrant and can be orally administered. It has been subject to investigation in Alzheimer's Disease and Progressive Supranuclear Palsy. More than 480 patients have been exposed to tideglusib for more than a year and preliminary results suggest some favorable effects on brain volume and downstream targets (e.g. Höglinger et al., 2014, Martinez et al., 2011). It has been generally well tolerated.

Objectives: TO evaluate the efficacy of tideglusib vs. placebo for the treatment of core symptom domains in adolescents with ASD.

Methods: This is a phase II randomized, placebo controlled, multisite trial. Participants were recruited across 3 sites and were randomized to drug or placebo in 1:1 fashion. Safety was evaluated using the SMURF, safety blood work and ECG. Efficacy was evaluated using the ABC – SW as a primary measure. Secondary measures included the Vineland-II, YBOCS, RBS-R as well as measures of anxiety, sleep and parent chief complaint. pK data was collected using a sparse sampling method. Biomarkers in the AKT-ERK pathway, as well imaging markers were explored.

Results:

83 participants were randomized across 3 sites. Tideglusib was well tolerated with no related serious adverse events reported. One participant was discontinued due to elevated liver enzymes. Final efficacy data as well as pharmacokinetics, pharmacodynamics and biomarkers predicting response will be presented.

Conclusions: Tideglusib, a GsK-3β inhibitor, was well tolerated in adolescents with ASD. Efficacy and biomarker data will also be presented

Oral Session - 15B
International and Cross-Cultural Perspectives
197 - International and Cross Cultural Perspectives
2:40 PM - 3:30 PM - Arcadis Zaal

2:40 **197.001** Universal Developmental Surveillance for Autism in Infants, Toddlers and Preschoolers: The Social Attention and Communication Study-Revised (SACS-R) and SACS-Preschool

J. Barbaro, *C. Dissanayake and N. Sadka, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia*

Background: Barbaro and Dissanayake (2010) utilised developmental surveillance for the early identification of autism within the Social Attention and Communication Study (SACS), where Maternal and Child Health (MCH) nurses were trained to monitor children for autism during routine, community-based health-checks between 12-24 months. The SACS had a positive predictive value (PPV) of 81%, and estimated sensitivity and specificity of 83.8% and 99.8%, respectively. However, all 20,770 children monitored were not followed-up at a later age to identify any false-negatives.

Objectives: The objectives of the current study were to: 1) improve the SACS' psychometric properties through use of the SACS-Revised (SACS-R) at children's routine, community-based health-checks from 12-24 months; 2) follow-up all children monitored with the SACS-R at 3.5 years to confirm diagnoses and identify false-negatives; and 3) investigate the psychometric properties of the newly added SACS-Preschool (SACS-PR) check at 3.5 years.

Methods: The SACS-R and SACS-PR contain brief checklists of key social-communication markers of autism at 12-, 18-, 24-, and 42-months-of-age, with 200 MCH nurses trained to utilise these checklists during their routine consultations. A total of 13,838 children were monitored on the SACS-R between 12- to 24-months, with all children identified at 'high likelihood' for autism referred for a developmental assessment with the SACS team. Children were assessed by the team every 6 months until 2 years, with gold-standard assessment tools (ADOS-Toddler, Mullen Scales of Early Learning, ADI-R). All children returned at 42 months to confirm diagnoses.

All children monitored by the MCH nurses between 12-24 months were also monitored with the SACS-PR at their 42-month consultation, with all children identified at 'high likelihood' for autism referred to the SACS team for an assessment. Furthermore, children identified as 'low likelihood' who had *any* developmental concerns, including autism, or had a community-based diagnosis of autism, were also referred for assessment with the SACS team to determine/confirm diagnoses.

Results: The nurses identified 323 children at 'high likelihood' for autism (2.3% referral rate) between 12- to 24-months using the SACS-R. Of these, 234 children have been assessed, with 192 children meeting criteria for ASD (82.4% PPV); the remaining children had developmental and/or language delays. Thus, no "true" false positives (typically developing children) were identified using the SACS-R. 72% of 12-month-olds, 82% of 18-month-olds, and 85% of 24-month-olds met criteria for autism, confirmed at 42-months-of-age. Sensitivity and specificity of the SACS-R was 72.3% and 99.6%, respectively, and Negative Predictive Value (NPV) was 97.7%. Nurses are currently monitoring children at their 42-month-check with the SACS-PR; thus, psychometric properties of the SACS-PR will be presented at the conference. Prevalence rates of autism found in the sample so far is 2.7%.

Conclusions: Developmental surveillance using the SACS-R continues to be the most effective method for the early identification of autism available. Its PPV is higher than the original SACS, with excellent NPV, specificity and sensitivity. These data confirm that developmental surveillance using the SACS-R is the most effective way to identify infants and toddlers with autism, with follow-ups using the SACS-PR useful in identifying 'false negatives'.

2:52 **197.002** Pilot Randomised Controlled Trial of the Who Caregiver Skills Training in Public Child Neuropsychiatry Services in Italy

E. Salomone[1,2]*, M. Settanni*[1]*, F. Ferrara*[1]*, A. Salandin*[1]*, T. WHO CST Team*[2]*, T. CST Italy Team*[1] *and C. Servili*[2]*, (1)Department of Psychology, University of Turin, Turin, Italy, (2)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland*

Background: Access to publicly-available, evidence-based early intervention for ASD is very limited even in high-income European countries, including Italy. The WHO Caregiver Skills Training (CST) program is evidence-based and meets affordability and feasibility criteria for implementation in public health settings. Following a formative adaptation process and pre-pilot implementation showing good acceptability and appropriateness to the local context, a pilot randomized controlled trial (RCT) of the WHO CST was conducted in rural and low-resourced urban areas in Northern Italy.

Objectives: to examine acceptability and feasibility of community-implemented CST; to pilot RCT processes.

Methods: The study is a two-arm pilot RCT of CST against enhanced treatment as usual (eTAU: one psychoeducation session in addition to TAU). Research assessments are at baseline, 3-month endpoint, and 9-month follow-up. Families were recruited in two waves through public Child Neuropsychiatry Services. Inclusion criteria were: clinical diagnosis of ASD; age 2-5 years; caregiver with sufficient level of Italian language to benefit from the intervention. Following baseline ascertainment (assessments of child autism severity and cognitive ability), participants were randomly assigned to either CST or eTAU on a 1:1 allocation ratio using stratified randomisation by age and autism severity. The CST program was delivered per manual by 6 pairs of local clinicians, who met CST fidelity criteria; CST group size varied from 5 to 8 families. Participation in the program was open to 1-2 caregivers per family; data were collected on the target caregiver/child dyad. Feedback forms and focus groups were used to record the facilitator and caregivers' experience. Main outcomes reported will be caregiver/child interaction data, caregiver self-efficacy, wellbeing, stress and mental health, child language and adaptive behaviour. Analysis will be by intention-to-treat.

Results: A total of 88 caregiver/child dyads were referred to the study; two did not meet the age criterion. The remaining 86 caregiver/child dyads were enrolled and completed baseline assessments. Sample ethnicity was representative of the Regional population; 16% (n=14) were non-Italian. The randomisation was acceptable to families and effective; children in the two groups (CST, n=43 and TAU, n=43) did not differ by age, autism severity or cognitive ability (ps ranged .786-.802). At the time of submission, CST attendance, endpoint and follow-up data were available only for Wave 1 participants (n=44: CST, n=22 and TAU, n=22). In the CST group, 82% of the target caregivers completed at least 75% of the program and 87% reported adherence to home practice. One caregiver/child dyad dropped-out from the CST program; none dropped-out from the study. All data were complete and research assessments were acceptable. Blinding was maintained. Program materials and contents were considered acceptable by caregivers. Facilitators suggested further adaptation of materials to strengthen psychoeducation messages on caregiver wellbeing and stigma reduction.

Conclusions: Preliminary data indicate that the RCT processes were successful; study retention was high in both groups; CST implementation in community setting (attendance rate; feasibility; acceptability) was satisfactory, suggesting that a full study can proceed. Final results, including treatment effects, will be available for presentation.

3:04 **197.003** Effects of Dual-Language Exposure on Language and Executive Function in Children with ASD and ADHD

A. B. Ratto[1]*, L. Anthony*[2]*, M. D. Powers*[3]*, A. Verbalis*[1]*, S. Seese*[1] *and L. Kenworthy*[1]*, (1)Children's National Health System, Washington, DC, (2)University of Colorado, Denver, Aurora, CO, (3)Children's National Health System, Rockville, MD*

Background: Dual-language exposure (DLE) has been linked to advantages in executive functioning (EF), particularly in cognitive flexibility, and reduced single-language vocabulary. However, there has been limited research on the effects of DLE on EF and language skills in clinical populations. Prior research indicates possible detrimental effects of DLE on EF and language skills in adults with ADHD, while DLE has not been shown to significantly impact EF or language skills in children with ASD.

Objectives:To investigate the effects of dual-language exposure on executive functioning and vocabulary in children with ASD and ADHD

Methods: Participants were drawn from a sample of 136 children (ages 8-11 years) from Title I schools, enrolled in a clinical trial of two EF interventions. All children met criteria for ADHD or ASD. Household income differed significantly by language exposure ($t(110)=5.51$, $p<.0001$). Using the case control matching application of SPSS 24, a final sample of 64 children (n=32 DLE) was created, matched on household income (within $5000). There were no significant differences in age, gender, diagnosis, or full-scale IQ on the Wechsler Abbreviated Scales of Intelligence-II (WASI-II) (Table 1). Parent education was significantly lower among DLE children ($t(60)=3.127$, $p=.003$), and thus was controlled for in all subsequent analyses. Vocabulary and EF were assessed using selected subtests of the WASI-II, the Verbal Fluency subtest of the Delis-Kaplan Executive Function System (D-KEFS), the Behavior Rating Inventory of Executive Functioning (BRIEF), and the Flexibility Interference Scale (FIS), a parent rating scale of daily difficulties due to cognitive rigidity.

Results:Hierarchical regression analyses were used to assess differences in EF and language skills by DLE, after controlling for both parent education and child diagnosis, in separate steps. Parent education significantly predicted language skills (WASI-II Vocabulary, F=12.393, p=.001; D-KEFS Category Fluency F=7.328, p=.009), and child diagnosis was associated with language skills at a level approaching significance; however, after controlling for parent education and diagnosis, DLE had no significant effect on language skills (Table 2). After controlling for parent education and diagnosis, DLE was associated with higher EF, including significantly less parent-reported interference from cognitive rigidity on the FIS (F=7.412, p=.009), as well as fewer difficulties with transitions and tolerating change on the BRIEF: Shift subscale (F=3.495, p=.067) and better flexible problem-solving on the WASI-II: Block Design (F=3.668, p=.060), at a level approaching significance (Table 2). After controlling for multiple comparisons, the effects of DLE on the BRIEF: Shift and WASI-II: Block Design were not significant. DLE was not significantly associated with behavioral regulation skills (BRIEF), metacognitive skills (BRIEF), or verbal switching skills (DKEFS; Table 2).

Conclusions: Although concerns about detrimental effects of DLE on language skills are common, the present study adds to prior findings indicating that DLE does not negatively impact language skills in children with neurodevelopmental disorders. Findings also indicate that DLE may have beneficial effects for EF skills in this population, consistent with findings in typically-developing samples. Overall, this study brings into question “common wisdom” that parents of children with neurodevelopmental disorders should limit their children’s exposure to other languages.

3:16 **197.004** Identifying Cultural Differences and Commonalities in Autistic Traits across India, Japan and the UK Using the Autism-Spectrum Quotient (AQ)

S. Carruthers[1], *E. Kinnaird*[2], *A. Rudra*[3], *P. Smith*[4], *C. Allison*[5], *B. Auyeung*[6], *B. Chakrabarti*[7], *A. Wakabayashi*[8], *S. Baron-Cohen*[5], *I. Bakolis*[2] *and R. A. Hoekstra*[9], *(1)King's College London, London, United Kingdom of Great Britain and Northern Ireland, (2)King's College London, London, United Kingdom, (3)Psychology, Ben Gurion University of the Negev, Beer Sheva, Israel, (4)University of Cambridge, Cambridge, United Kingdom, (5)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (6)University of Edinburgh, Edinburgh, United Kingdom, (7)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (8)Chiba University, Chiba, Japan, (9)Department of Psychology, King's College London, London, United Kingdom*

Background: There is a global need for brief open-source screening instruments that can identify “red flags” for autism spectrum disorder (ASD) and support frontline professionals in their referral decision-making (Durkin et al., 2015). Though generally believed to be a universal disorder, there may be subtle differences in identification or reporting of ASD symptoms across cultures. In order to assess the potential for any measure to be adapted for cross-cultural screening use, it is important to understand the relative performance of such measures in different cultures.

Objectives: Our study aimed to identify and compare the items on the Autism-Spectrum Quotient (AQ)-Child (Auyeung et al., 2008) most predictive of an ASD diagnosis among children aged 4-9 years across different samples from India, Japan and the UK.

Methods: Parent-reported AQ-Child data were collected from 73 children with a formal ASD diagnosis and 81 neurotypical children from India (previously reported in Rudra et al., 2014); 116 ASD and 190 neurotypical children from Japan (data not previously reported), and 488 ASD and 532 neurotypical children from the UK (some data previously reported in Allison et al., 2012). None of the children included had a reported diagnosis of intellectual disability. Participants from each country were randomly allocated to derivation and validation samples. For each item, Discrimination Indices (DI) and Positive Predictive Values (PPV) were calculated using the derivation and validation samples respectively. Items surpassing a discrimination index (DI) threshold of 0.5 and a positive predictive value (PPV) of 0.7 within each country were considered highly discriminative for that culture. Such items were compared across cultures. The psychometric validity of the “red flag items” was assessed using Receiving Operating Curves (ROC curves), discriminant analysis, Cronbach’s alpha and Pearson’s correlation coefficient.

Results: 16 items in the Indian sample, 15 items in the Japanese sample and 28 items in the UK sample demonstrated excellent predictive ability of an ASD diagnosis. Five items surpassed the high discrimination threshold ($DI \geq 0.5$, $PPV \geq 0.7$) in all three samples. One item (‘When s/he talks, it isn’t always easy for others to get a word in edgeways’) was highly discriminative in Japan but poorly discriminative ($DI<0.3$) in the UK and India, and a further item (S/he enjoys doing things spontaneously) had excellent discrimination properties in the UK but poorly discriminated in the Indian and Japanese samples. Two additional items were highly discriminative in two cultures but poor in the third.

Conclusions: In a cross-cultural study of children with intelligence in the normal range, there was cross-cultural overlap in the items most predictive of an autism diagnosis, supporting the notion of global universality in autistic traits and the possibility of adapting an existing tool for cross-cultural screening. Subtle cultural differences were suggested in four items, which may be related to contrasting sociocultural values and attitudes such as social conformity and uncertainty avoidance (Hofstede, 2001). These findings can inform the development of a brief “red flag” global screening tool for ASD.
