We present CoTe₂ as a type-II Dirac semimetal supporting Lorentz-symmetry violating Dirac fermions in the vicinity of the Fermi energy. By combining first-principles *ab initio* calculations with experimental angle-resolved photoemission spectroscopy results, we show CoTe₂ hosts a pair of type-II Dirac fermions around 90 meV above the Fermi energy. In addition to the bulk Dirac fermions, we find several topological band inversions in bulk CoTe₂, which gives rise to a ladder of spin-polarized surface states over a wide range of energies. In contrast to the surface states which typically display Rashba-type in-plane spin splitting, we find that CoTe₂ hosts interesting out-of-plane spin polarization as well. Our work establishes CoTe₂ as a potential candidate for the exploration of Dirac fermiology and applications in spintronic devices, infrared plasmonics, and ultrafast optoelectronics.

I. INTRODUCTION

The broad class of layered transition metal dichalcogenides (TMDs) has attracted significant attention in the last decades due to their novel electronic, optical, and topological properties, combined with their potential for various applications [1–7]. Owing to the weak interlayer van der Waals interaction, TMDs offer easy exfoliation of isolated monolayers which host different physical properties from their bulk counterpart. Interesting examples of this include the quantum spin Hall effect, superconductivity, charge density wave, and various topological phases [8–21]. The physical and chemical properties of TMDs can be tuned by the selection of the constituents, the crystal structures, and the layer thicknesses [22–28]. Specifically, among the TMX_2 family of TMDs, PdTe₂, PtTe₂, PtSe₂, and NiTe₂ have attracted notable interest due to the observation of Lorentz-symmetry violating, type-II Dirac fermions associated with a tilted Dirac cone near the Fermi energy [13,18,28–38]. The Lorentz-symmetry breaking type-II Dirac fermions have electronic, optical, and other physical properties which are different from those found in other topological semimetals. The electronic band structure and spin-polarized topological surface states in these materials have been thoroughly investigated by combining realistic *ab initio* calculations with spin-resolved and conventional angle-resolved photoemission spectroscopy (ARPES) experiments.

However, the electronic properties of another prospective candidate material in the series, CoTe₂, are yet to be explored [39]. CoTe₂ can crystallize in both trigonal ($P\bar{3}m1$) and orthorhombic ($Pnn2$ and $Pnnm$) forms. Among these, centrosymmetric trigonal 1T-CoTe₂ has recently been shown to be a highly efficient electrocatalyst for water splitting [40,41]. In this paper, we present a detailed investigation of the electronic structure of 1T-CoTe₂ by combining first-principles calculations with spin-polarized ARPES experiments. We find that similar to other TMX_2 compounds, CoTe₂ is also a topological semimetal supporting a type-II Dirac crossing in the vicinity of the Fermi energy. In addition to the bulk electronic structure, we demonstrate that CoTe₂ hosts a ladder of topological surface states arising from several topological band inversions in the bulk electronic structure. These give rise to spin-polarized Dirac surface states, with a large spectral weight. We probe this via spin-ARPES measurements and the measured spin-polarized states are consistent with our spin-dependent spectral function calculations. Interestingly, we find that some of the surface states, away from the $\bar{\Gamma}$ point, have an out-of-plane spin polarization.

The rest of the paper is organized as follows. We describe the crystal structure and computational details in Sec. II, followed by the details of the spin-ARPES measurements in Sec. III. In Sec. IV, we explore the band structure and geometry of the Fermi surface (FS) in CoTe₂. We study the origin of the Dirac states, multiple band inversions, and their origin in CoTe₂ employing the ARPES measurements combined with *ab initio* electronic structure calculations in Sec. V.

[a]Topological Quantum Chemistry Database.

In Sec. VI, we discuss the spin-polarized surface states and the existence of unique out-of-plane spin-polarized states in CoTe₂ calculations. We summarize our findings in Sec. VII.

II. CRYSTAL STRUCTURE AND THEORETICAL METHODS

Bulk CoTe₂ crystallizes in a CdI₂-type trigonal structure that belongs to the space group $P\bar{3}m1$ (No. 164). Each unit cell of CoTe₂ has one Co atom and two Te atoms. To obtain the minimum-energy structure for CoTe₂, we performed the symmetry-protected cell volume and ion relaxation using the conjugate-gradient algorithm until the Hellman-Feynman forces on each atom were less than the tolerance value of 10^{-4} eV/Å. The cell volume of the experimental structure increased by 2.5% as a result of the relaxation. A comparison of lattice parameters between experimental and theoretically relaxed structures is presented in Table I.

The trigonally distorted CoTe₆ octahedra accommodating the nearest-neighbor Co-Te bonds (∼2.55 Å) form an edge shared geometrical network on the crystallographic *a-b* plane [see Figs. 1(a) and 1(b)]. Adjacent monolayers, stacked along the *c* axis, interact via a weak van der Waals interaction. Figure 1(d) shows the corresponding bulk and (001) surface Brillouin zones (BZs) along with the high-symmetry points. The CoTe₂ crystal structure possesses threefold rotational symmetry around the *z* axis (C_3), inversion symmetry *I*, and three mirror symmetries M_{100}, M_{010}, and M_{110}. Figure 1(e)

shows the experimental x-ray diffraction pattern for CoTe₂. The observation of sharp white spots in the Laue diffraction pattern in the inset of Fig. 1(e) confirms the high quality of the CoTe₂ crystals cleaved along the (0001) direction. The presence of threefold rotation symmetry is also evident.

To perform the *ab initio* calculations, we used the density functional theory (DFT) in the plane-wave basis set. We used the Perdew-Burke-Ernzerhof (PBE) [42] implementation of the generalized gradient approximation (GGA) for the exchange correlation. This was combined with the projector augmented-wave potentials [43,44] as implemented in the Vienna *ab initio* simulation package (VASP) [44,45]. GGA calculations were carried out with and without the Coulomb correlation (Hubbard *U*) and spin-orbit coupling (SOC). The SOC is included in the calculations as a second variational form to the original Hamiltonian. The kinetic energy cutoff of the plane-wave basis for the DFT calculations was chosen to be 450 eV. A Γ-centered $12 \times 12 \times 8$ Monkhorst-Pack [46] *k*-point grid was used to perform the momentum-space calculations for the Brillouin zone (BZ) integration of bulk. To calculate the surface spectral function for finite geometry slabs of CoTe₂, we construct the tight-binding model Hamiltonian by deploying atom-centered Wannier functions within the VASP2WANNIER90 [47] codes. Utilizing the obtained tight-binding model, we calculate the surface spectral function using the iterative Green's function method, as implemented in the WANNIERTOOLS package [48].

III. ARPES AND SPIN-ARPES MEASUREMENTS

ARPES and spin-ARPES measurements were performed at the low-energy (LE) branch of the APE-NFFA beamline [49] at the Elettra synchrotron facility (Trieste, Italy), which is equipped with VESPA [50] as an electron spin polarization detector. The details of the experimental geometry, such as the electron analyzer slit opening and incoming photon direction with respect to the analyzer lens axis, can be found in Ref. [50]. To determine the inner potential (V_0) of CoTe₂

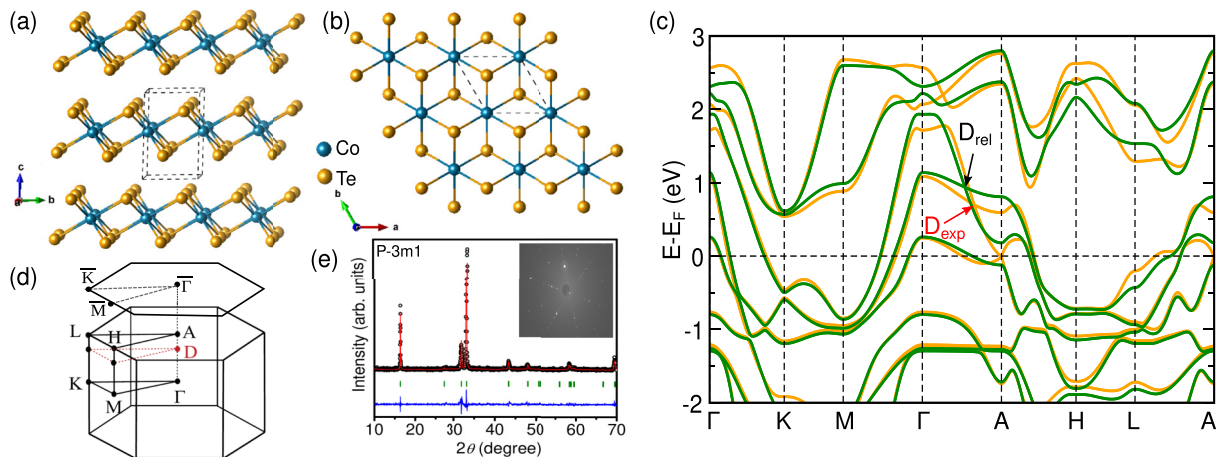

FIG. 1. (a) Side and (b) top views of the CoTe₂ crystal. In the presence of SOC, the band dispersion of the experimental (orange) and relaxed (green) structures are plotted along the high-symmetry paths, marked in the Brillouin zone shown in (d). The type-II Dirac crossings near the Fermi energy of the experimental (D_{expt}) and relaxed (D_{rel}) structure are marked with red and black arrows. (e) The x-ray diffraction peak structure for CoTe₂. The inset shows a Laue pattern of the (0001)-oriented CoTe₂ single crystals, clearly indicating its purity and the threefold symmetry along the (001) direction.
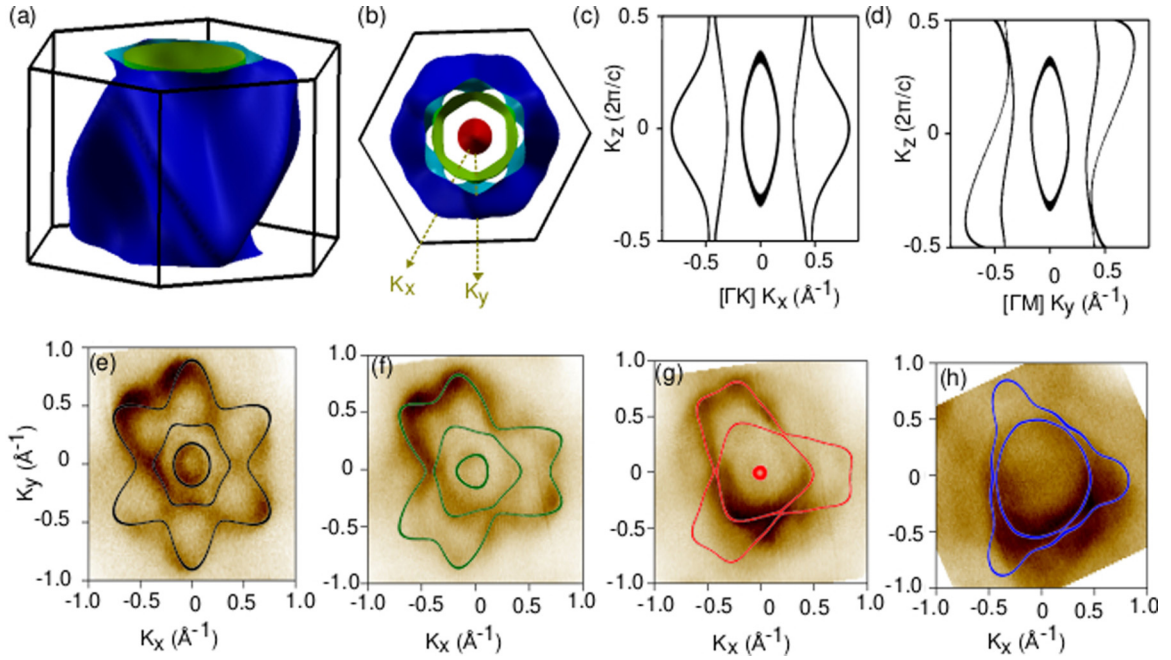

FIG. 2. (a) Side and (b) top views of the 3D FS. The projected FS at $E = E_F$ on the (c) K_x-K_z plane along Γ-K and (d) K_y-K_z plane along Γ-M directions. The experimentally measured 2D energy contours over the K_x-K_y plane at fixed values (e) $K_z = 0.03c^*$, (f) $K_z = 0.16c^*$, (g) $K_z = 0.29c^*$, and (h) $K_z = 0.42c^*$, where $c^* = 2\pi/c$. The theoretical FS cuts for specific K_z planes are plotted on top of the corresponding experimental results.

(0001) experimentally, angle-resolved valence band spectra and FS maps were measured for the photon energy range between 13 and 85 eV with two linear polarizations (s and p polarization). Spin-ARPES maps were acquired for two-photon energies ($h\nu = 19$ and 75 eV). The energy and angular resolutions for the spin-ARPES measurements were set to 100 meV and 1.5°, respectively. The clean (0001) surface of CoTe$_2$ was obtained by cleavage of the single crystal *in situ* in an ultrahigh vacuum. The sample temperature during the ARPES and spin-ARPES measurements was kept at 78 K.

IV. ELECTRONIC BAND STRUCTURE AND FS GEOMETRY

The ionic balance of the chemical formula of CoTe$_2$ suggests that the Co and Te atoms are in $3d^3 4s^0$ and $5s^2 5p^6$ configurations, respectively. As a consequence, we expect the Co d and Te p orbitals to have a major contribution at the Fermi energy (E_F). We present the bulk band dispersion in the presence of SOC, for the experimental structure, and also for the relaxed structure in Fig. 1(c). The experimental electronic band dispersion in Fig. 1(c) clearly shows the existence of a couple of tilted Dirac-like crossings just above E_F, along the Γ-A high-symmetry direction. We find that the position of the Dirac point (DP) is sensitive to small variations of the structural parameters. It shifts from ~0.68 to ~0.92 eV above E_F due to the small change in the structural parameters on relaxation. Since the Γ-A path is an invariant subspace of the threefold rotational crystal symmetry (C_3), the Dirac cone is protected by rotational symmetry. This is similar to the Dirac crossing in NiTe$_2$ and other related materials in the same space group [18,34,51]. Two accidental linear band crossings, one exactly at E_F on the high-symmetry A point and another one

at ~2.2 eV above E_F along the Γ-A path, become gapped due to relaxation, as highlighted in Fig. 1(c).

The geometry of the FS and its evolution with change in the Fermi energy is shown in Fig. 2 for the relaxed structure. The three-dimensional (3D) FS for $E = E_F$ is shown in Fig. 2(a). The projection of the FS on a plane perpendicular to the K_z axis in Fig. 2(b) clearly shows three distinct types of band contributions at the FS, each having twofold degeneracy. Figures 2(c) and 2(d) capture the projection of the FS on the K_x-K_z plane along the Γ-K line, and the K_y-K_z plane along the Γ-M direction. The FS along the Γ-M path is highly anisotropic as seen in Fig. 2(d). Clearly, bulk CoTe$_2$ has a strong momentum-dependent anisotropic FS (see Appendix B for details), which is also expected from the presence of type-II Dirac fermions in the system. To investigate the FS modulations along the K_z direction, we have shown the energy contours at different K_z values in Figs. 2(e)–2(h). The theoretically calculated (solid line) and the experimentally measured (mud colored scale) two-dimensional (2D) energy contours within the Wigner-Seitz cell are shown in Figs. 2(e)–2(h) over the K_x-K_y plane for different K_z values. Different K_z values are probed in the ARPES experiment by changing the energy of the incident photon beam. Using the free-electron final state model [52], we have

$$k_\perp = \frac{1}{\hbar}\sqrt{2m(V_0 + E_{kin}\cos^2\theta)}. \qquad (1)$$

Here, V_0 is the inner potential, E_{kin} is the kinetic energy of a photoelectron, and θ denotes the emission angled from the sample surface normal. For the different panels of Figs. 2(e)–2(h), we have $h\nu$ (corresponding K_z) = 75 eV ($0.03c^*$), 70 eV ($0.16c^*$), 65 eV ($0.29c^*$), and 60 eV ($0.42c^*$), respectively,
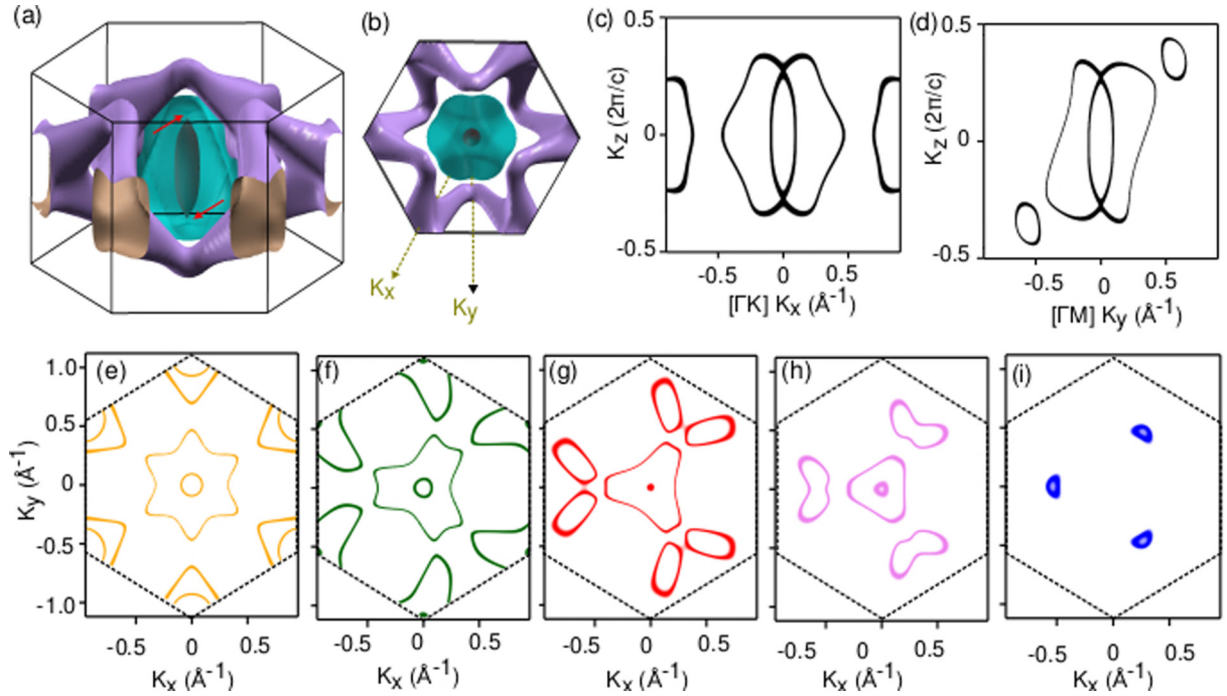

FIG. 3. (a) Side and (b) top views of the 3D FS distribution. The planar projection of the constant energy surface at $E - E_F = 0.94$ eV, on the (c) K_x-K_z and (d) K_y-K_z surface. The 2D energy contours within the Wigner-Seitz cell (marked by a dotted line) in the K_x-K_y plane at fixed K_z values of (e) $K_z = 0$, (f) $K_z = 0.15c^*$, (g) $K_z = 0.25c^*$, (h) $K_z = 0.30c^*$, and (i) $K_z = 0.42c^*$, where $c^* = 2\pi/c$. The 2D plane of (g), which hosts the Dirac point, is marked in Fig. 1(d).

where $c^* = 2\pi/c$. We have applied $V_0 = 11$ eV to calculate the K_z values.

The experimental FS demonstrates the transformation of its symmetry from sixfold at $K_z = 0$ to threefold for $K_z > 0$, which is consistent with the theoretical calculations. For $K_z = 0$ [Fig. 2(e)], all three (the hexapetalus flower-shaped, hexagonal, and circular) states are observed and well matched to the calculated FS. The hexapetalus flower-shaped states in Fig. 2(e) are transformed into the trefoil in Fig. 2(f). Due to the experimental geometry and the corresponding matrix-element effect, the measured FS shows an anisotropic distribution in the photoemission intensity. The photoemission intensity is higher along one of the three $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions and lower along the two other $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions. This effect reduces the clarity of the threefold symmetry in the FS, measured for Figs. 2(g) and 2(h). However, the strong modulation of the FS on changing K_z is clear, and it is broadly consistent with the 3D FS distribution of Fig. 2(a).

We now focus on the FS, in the vicinity of the DP. The side and top views of the 3D FS distribution within the Wigner-Seitz cell at $E = E_{DP}$ for the relaxed structure are presented in Figs. 3(a) and 3(b), respectively. The presence of three contributing bands, each having twofold Kramer's degeneracy, can be clearly seen. The outermost part of the FS arises from the electron pocket of the first unoccupied band of $CoTe_2$, as seen in Fig. 1(c). The type-II nature of the Dirac semimetal (DSM) phase is also confirmed by the fact that the Dirac point appears at the fourfold degenerate touching point of the other electron and hole pockets in the middle, as marked by the red arrow in the FS in Fig. 3(a). The energy contours over the K_x-K_z and K_y-K_z planes, for $E = E_{DP}$, are

shown in Figs. 3(c) and 3(d), respectively. Our calculations reveal a prominent Dirac crossing located at $K_z \sim \pm 0.25c^*$. The anisotropic nature of the FS along the K_y direction persists even at the DP. The in-plane projections of the energy contours at the DP are presented in Figs. 3(e)–3(i), for five different out-of-plane distances (or K_z values). At $K_z = 0c^*$, we observe a hexapetalus flower shape along with a small circle at its center. The electron pockets at $K_z = 0$ transform into an isolated bean-shaped pattern with increasing K_z magnitude as seen in Figs. 3(g)–3(i). At K_z approaching the vicinity of bulk DP, the central contour converges to a tiny circle while the hexagonal outer contour acquires an almost triangular shape [see Figs. 3(g) and 3(h)]. Finally, at $K_z = 0.3c^*$, the FS cut appears as two contours centered around the origin, which exhibit a circular and triangular shape for the inner and outer contours, respectively. In addition, there are small pockets along three of the six A-H lines [see Fig. 3(h)]. The energy contour at negative K_z values with the same magnitude shows the rest of the three small pockets along the other A-H lines. In Fig. 3(i) the inner contours vanish and we only see three small pockets along the A-H direction.

V. ORIGIN OF DIRAC STATES, BAND INVERSION, AND SURFACE STATES

The presence of type-II Dirac fermions in the bulk dispersion of $CoTe_2$ suggests the strong possibility of finding topologically protected surface states near the Fermi energy. Additionally, the bulk bands of $CoTe_2$ also support several other topological band inversions in its bulk. In Fig. 4(a), the orbital-resolved band structure along the Γ-A path shows
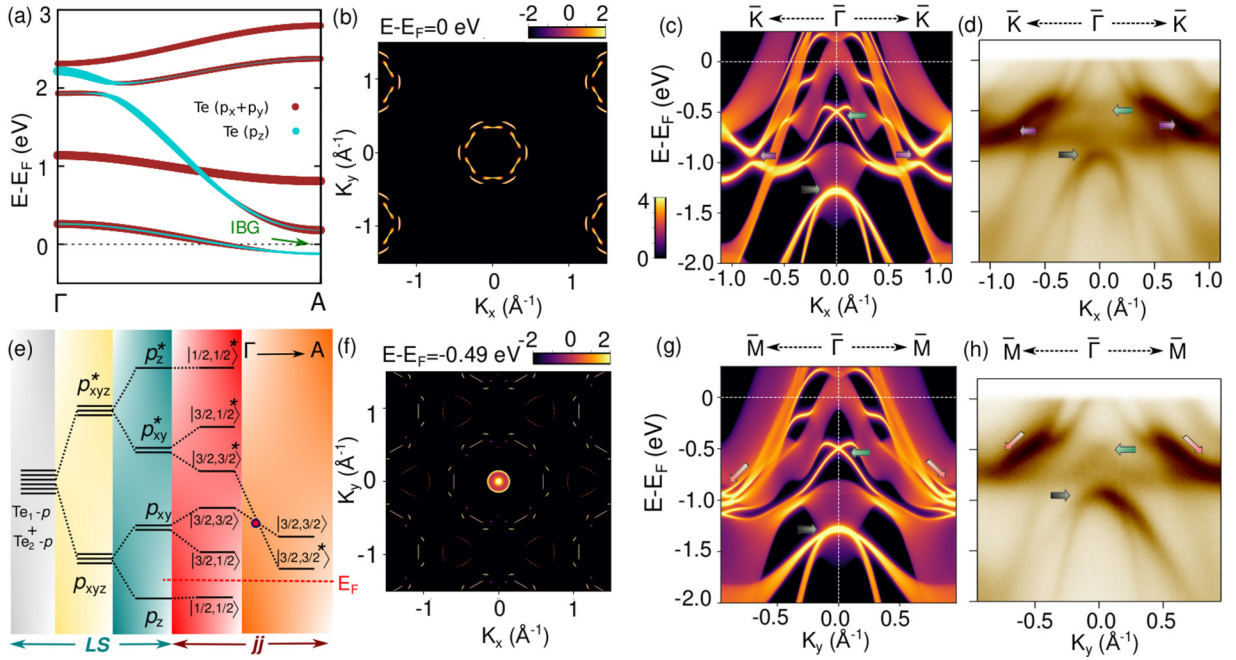

FIG. 4. (a) Multiple band inversion arising from the Te p orbital manifold along the Γ-A direction. The band inversion gap near the Fermi energy (IBG) is marked with an arrow. The Fermi arc states at constant energy (b) $E - E_F = 0$ and (f) $E - E_F = -0.49$ eV. The theoretically calculated momentum-resolved spectral density plot along the (c) $\bar{\Gamma}$-$\bar{K}$ and (g) $\bar{\Gamma}$-$\bar{M}$ paths. The experimentally measured ARPES plots along the (d) $\bar{\Gamma}$-$\bar{K}$ and (h) $\bar{\Gamma}$-$\bar{M}$ paths. (e) To highlight the origin of the bulk type-II Dirac fermions, we show the schematic of the level diagram of the Te $5p$ orbitals in the presence of a local crystal field and SOC.

that the linear crossings near E_F are mainly composed of Te $5p$ orbitals. The Dirac band crossing near 0.92 eV above the Fermi energy arises from the interplay of the Te $p_x + p_y$ and the Te p_z orbitals. Additionally, we find that these orbitals also contribute to multiple band inversion gaps along different high-symmetry paths including Γ-A [see Fig. 4(a)]. To understand the origin of the Dirac band crossing, we show the systematic evolution of the energy levels of the Te $5p$ orbital manifold in Fig. 4(e). The six degenerate p orbitals split into lower (upper) lying threefold bonding (antibonding) orbitals due to intersite hybridization. The presence of local trigonal distortion of the Co-Te octahedra further lifts the degeneracy of the bonding/antibonding p orbitals, breaking them into singly degenerate a_{1g} (p_z) and doubly degenerate e_g^π (p_x, p_y) orbitals. Including the SOC splits the p orbitals into fourfold $J_{\text{eff}} = 3/2$ and twofold $J_{\text{eff}} = 1/2$ pseudospin bases as shown in the fourth column of Fig. 4(e). The last column of Fig. 4(e) highlights the effect of the dispersion along the Γ-A direction. The bulk type-II Dirac point arises from the crossing of the bonding and antibonding states of the $J_{\text{eff}} = 3/2$ orbitals.

The ladder of multiple band inversions and the Dirac point in the bulk band structure points to the existence of topologically protected surface states in CoTe$_2$. This is confirmed by our experiments and theoretical calculations. The measured ARPES results and the corresponding theoretical spectral function of the relaxed structure are shown along the high-symmetry $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ and $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions in Figs. 4(c) and 4(d) and Figs. 4(g) and 4(h), respectively. The pattern of the spectral function and position of the surface Dirac cone matches well between the theoretical calculations and experimental plots. However, the other sharp spectral functions (as marked by purple arrows in Figs. 4(c), 4(d) and yellow arrows in

Fig. 4(g)) arising from the bulk and surface states are slightly off in energy (see Appendix A for detailed discussions). This can be due to several reasons including (i) small variations in the structural parameters, (ii) some ambiguity in the pseudopotential for capturing core states, and (iii) some impurities or stacking faults in the crystal which are not included in theoretical calculations, among others. We also note that as the bulk Dirac cone is significantly above the Fermi energy, as it cannot be directly observed or mapped via our occupied state ARPES data.

The ARPES measurements were done with $h\nu = 75$ eV, which corresponds to $K_z \sim 0c^*$. Therefore these spectra capture the bulk bands along with the surface states. The prominent features corresponding to the surface states, in the measured ARPES spectrum and the calculated spectral function, are marked by thick arrows. Despite some discrepancies in the binding energy of a few states, the experimental and the theoretical results show good qualitative agreement. The small energy difference in the location of the surface states possibly arises due to structural effects or from the surface potential which is not included in our theoretical calculations.

The Dirac cone in the surface states is located at the $\bar{\Gamma}$ point at an energy 0.49 eV below the Fermi energy. The presence of a topological band inversion near E_F, as marked by an arrow in Fig. 4(a), gives rise to this surface Dirac crossing observed in ARPES. A similar surface Dirac cone, which has relatively broad features in ARPES experiments compared to theoretical calculations, has also been observed in other isostructural compounds such as NiTe$_2$ and in PtTe$_2$. Other than the Dirac cone at the $\bar{\Gamma}$ point, several sharp nontrivial surface states appear near the high-symmetry $\bar{M}$ point and along the $\bar{\Gamma}$-$\bar{K}$ path. These arise from the multiple band inversions
FIG. 5. Spin polarization of the surface bands along the high-symmetry (a) $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ and (c) $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions. The spin-ARPES measurements for the (b) $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ and (d) $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions. The spin components are orthogonal to the corresponding momentum directions. (e) The theoretical and (f) experimentally measured out-of-plane spin polarizations along the $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ direction. CoTe$_2$ supports spin-polarized surface states over a wide range of energies in the entire BZ.

throughout the BZ. We find the surface states to be symmetric along both $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ and $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions.

The Fermi arc states at constant energy are plotted in Fig. 4(b) at $E - E_F = 0$ eV and in Fig. 4(f) at $E - E_F = -0.49$ eV. At the Fermi energy, circular arcs of the sharp surface states appear around the $\bar{\Gamma}$ point. In contrast, a prominent peak is observed exactly at the $\bar{\Gamma}$ point in Fig. 4(f) which captures the dominant surface Dirac, crossing along with a few less intense circular arcs along the $\bar{\Gamma}$-$\bar{K}$ paths. There is another set of high-intensity surface arc states around -1.4 eV below E_F [see Figs. 4(c) and 4(g)], which disperse symmetrically around the $\bar{\Gamma}$ point.

VI. SPIN-POLARIZED SURFACE STATES

The demonstration of topological surface states in CoTe$_2$ inspires the exploration of their spin polarization. To study the spin polarization of the surface states and the surface Dirac cone, we experimentally measured the spin-polarized ARPES spectrum of CoTe$_2$, as shown in Figs. 5(b), 5(d) and 5(f). The component of probed spin components is chosen to be perpendicular to the direction of the dispersion. The corresponding theoretically calculated spin-resolved spectral function is shown in Figs. 5(a), 5(c) and 5(e). Figures 5(b) and 5(d) display the measured spin-resolved band structures superimposed onto the measured spin-integrated band structures shown in Figs. 4(d) and 4(h), along $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ and $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$, respectively. As was seen in the experimental plots of Figs. 4(d) and 4(h), the surface Dirac cone spectral intensity is relatively low compared to the observed bulk states for the photon energy $h\nu = 75$ eV. Accordingly, its contribution to the measured spin-ARPES spectra is also small. To improve the resolution of the spin information of the surface Dirac cone, the spin-ARPES spectra in Fig. 5(d) were measured with $h\nu = 19$ eV. The crossings of the up-spin (red) and the down-spin (blue) bands are well observed around the energy of the surface Dirac point, matching well with the calculated spin texture shown in Fig. 5(c). This confirms the helical nature of the spin-momentum locking around the surface Dirac point and its topological origin. The signs of the measured and calculated spin polarization are reversed for $K_{x/y} \rightarrow -K_{x/y}$, in

all panels. This implies that the spin polarization is not due to the breaking of time-reversal symmetry.

Interestingly, we also observe a significant contribution of the out-of-plane component in our spin-ARPES experiments and calculations for the $\bar{K}$-$\bar{\Gamma}$-$\bar{K}$ direction, as shown in Figs. 5(e) and 5(f). The measurement is done with incident photons with energy $h\nu = 75$ eV. The corresponding out-of-plane spin component for the $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ direction is negligibly small. The scale of the in-plane and the out-of-plane spin polarizations in all the panels is identical. Note that due to the presence of time-reversal and inversion symmetry in CoTe$_2$, the spin polarization of the bulk states is forbidden. Even an isolated monolayer of CoTe$_2$ preserves the inversion and the time-reversal symmetries. Thus, an isolated monolayer of CoTe$_2$ will also not support spin-polarized states. However, in a system of finite size, the inversion symmetry is broken for the atomic layers near the surface even for bulk centrosymmetric systems. This is what allows for spin polarization of the surface states (both in plane and out of plane) in a finite slab of CoTe$_2$, and other Dirac semimetals. Another interesting point is that the surface states near the $\bar{\Gamma}$ point primarily arise from the topological bulk band inversions, and these lead to Dirac surface states which have an in-plane Rashba-like spin-momentum locking. This can be clearly seen in Fig. 5(e), where the out-of-plane spin states are completely absent near the $\bar{\Gamma}$ point.

VII. CONCLUSIONS

In summary, based on the ARPES experiments combined with detailed first-principles calculations, we show that CoTe$_2$ hosts a pair of type-II Dirac nodes. The Dirac node is located along the Γ-A axis around 0.92 eV above the Fermi energy, and they support Lorentz-symmetry violating Dirac fermions. We find that in addition to the Dirac fermions, bulk CoTe$_2$ also hosts several topological band inversions which give rise to a ladder of spin-polarized surface states over a wide range of energies. The surface states corresponding to the bulk band inversions form a surface Dirac cone at the $\bar{\Gamma}$ point, which has Rashba-type in-plane spin splitting. Interestingly, we find that some surface states in CoTe$_2$ also support an out-of-plane
FIG. 6. (a) Theoretically calculated and (b) experimental momentum-resolved spectral function plot $\bar{M}$-$\bar{\Gamma}$-$\bar{M}$ directions. The theoretical spectral function incorporates an energy scaling factor of 0.7 to best match the experimental data.

spin polarization. Our study highlights that $CoTe_2$ supports interesting bulk and surface Dirac fermiology, which should be explored further in transport, optical, plasmonic, and optoelectronic experiments.
FIG. 7. The projected experimental Fermi surface at $E = E_F$ on the (a) K_x-K_z plane along where K_x is along the Γ-K direction, and on the (b) K_y-K_z plane with K_y being along the Γ-M direction. The black lines are the theoretically calculated 2D energy contours.

APPENDIX A: SCALED ARPES

The prominent bulk and surface states (except for the Dirac crossing) of theoretically calculated spectral function and experimentally measured ARPES plots in Figs. 4(c) and 4(d) and in Fig. 4(g) have an energy difference of ∼500 meV. This can arise from various factors as discussed in Sec. V. For example, a similar discrepancy of energy is reported for a related compound $PtSe_2$ in Ref. [53]. An energy scale factor of 1.05 and an energy offset of -0.1 eV is necessary for the $PtSe_2$ compound to correctly match the energy between theoretical and experimental ARPES results. Similarly in our calculation, an energy scaling of 0.7 can be used to best fit the experimental plot (see Fig. 6).

APPENDIX B: FERMI-SURFACE ANISOTROPY

In this Appendix, we have compared the theoretically calculated and experimentally observed Fermi-surface maps on K_x-K_z and K_y-K_z planes. In Fig. 7, we have plotted the theoretically calculated 2D energy contours at $E = E_F$ on top of the experimental results. Here, the anisotropy, as discussed in Sec. IV, is evident from the differences between the plots shown in Figs. 7(a) and 7(b). The experimental K_x-K_z and K_y-K_z maps are taken with the photon energy range between 55 and 85 eV.
